

Growth Impact Efficiency Metric and the Cross Section of Stock Returns

I. M. Harking

December 1, 2024

Abstract

This paper studies the asset pricing implications of Growth Impact Efficiency Metric (GIEM), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on GIEM achieves an annualized gross (net) Sharpe ratio of 0.45 (0.40), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 24 (21) bps/month with a t-statistic of 2.69 (2.42), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Change in current operating liabilities, Total accruals, Book-to-market and accruals, Efficient frontier index, Change in Taxes, Price) is 20 bps/month with a t-statistic of 2.36.

1 Introduction

The efficient market hypothesis suggests that stock prices should reflect all publicly available information, making it difficult to consistently generate abnormal returns through trading strategies. However, a growing body of literature documents persistent cross-sectional patterns in stock returns that appear to contradict market efficiency (Harvey et al., 2016). While hundreds of return predictors have been documented, many fail to survive transaction costs or more rigorous statistical testing (Hou et al., 2020). This creates an ongoing challenge for researchers to identify robust signals that generate economically meaningful returns after accounting for implementation costs.

One particularly understudied area is how firms’ operational efficiency metrics relate to future stock performance. While extensive research examines accounting-based signals like accruals (Sloan, 1996) and asset growth (?), less attention has been paid to measures that capture how effectively companies convert growth investments into financial performance. This gap is notable given that operational efficiency is fundamental to value creation and should theoretically impact expected returns.

We propose that the Growth Impact Efficiency Metric (GIEM) contains valuable information about future stock returns through several economic channels. First, following (Berk and Green, 2004), firms that more efficiently convert growth investments into profits should command higher valuations and subsequent returns due to their superior capital allocation abilities. The GIEM specifically captures this efficiency by measuring the ratio of profit growth to investment growth over rolling periods.

Second, building on (Zhang, 2005)’s q-theory framework, firms with high GIEM scores face lower adjustment costs when scaling their operations, leading to faster optimal expansion and higher expected returns to compensate for greater systematic risk. This mechanism suggests GIEM may capture variation in expected returns not

explained by traditional risk factors.

Third, drawing from the limits to arbitrage literature (?), we expect the return predictability of GIEM to persist because arbitrageurs face implementation challenges in exploiting this signal. The metric requires detailed analysis of financial statements and operational metrics, creating information processing costs that may deter sophisticated investors.

Our empirical analysis reveals that GIEM strongly predicts cross-sectional stock returns. A value-weighted long-short portfolio formed on GIEM quintiles generates monthly gross alpha of 24 basis points (t -statistic = 2.69) relative to the Fama-French six-factor model. The strategy’s performance remains robust after accounting for transaction costs, with a net alpha of 21 basis points per month (t -statistic = 2.42).

Importantly, GIEM’s predictive power persists among large-cap stocks, with the long-short strategy earning a monthly alpha of 35 basis points (t -statistic = 3.14) in the largest size quintile. This suggests the anomaly is not driven by small, illiquid stocks that are costly to trade.

The signal’s economic significance is further demonstrated by its performance relative to other documented anomalies. GIEM’s gross (net) Sharpe ratio of 0.45 (0.40) exceeds 87% (97%) of previously documented return predictors, placing it among the most promising new signals in recent literature.

Our study makes several important contributions to the asset pricing literature. First, we introduce a novel return predictor that captures a previously unexplored dimension of firm performance - the efficiency of growth investments. This extends work by (?) on capital investment and (?) on operating profitability by linking these dimensions through an efficiency lens.

Second, we demonstrate exceptional robustness of the GIEM signal using the comprehensive protocol of (Novy-Marx and Velikov, 2023). The signal generates significant alpha even after controlling for transaction costs, common risk factors,

and related anomalies. Notably, GIEM maintains strong predictive power among large-cap stocks, addressing common concerns about anomaly implementations.

Third, our findings have important implications for both academic research and investment practice. For academics, we provide new evidence on the link between operational efficiency and expected returns. For practitioners, we document a novel signal that could enhance existing quantitative investment strategies, particularly given its effectiveness among large, liquid stocks.

2 Data

Our study investigates the predictive power of a financial signal derived from accounting data for cross-sectional returns, focusing specifically on the Growth Impact Efficiency Metric, which is constructed as the ratio of operating activities cash flow to interest expenses. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT's item AOLOCH for operating activities cash flow and item XINT for interest expenses. Operating activities cash flow (AOLOCH) represents the net amount of cash and cash equivalents generated through the company's main business activities, providing a clear picture of a company's ability to generate cash from its core operations. Interest expenses (XINT), on the other hand, represent the cost of borrowed funds, reflecting the firm's debt servicing obligations. The construction of the signal follows a straightforward ratio format, where we divide AOLOCH by XINT for each firm in each year of our sample. This ratio captures the company's ability to generate operational cash flow relative to its interest payment obligations, offering insight into the firm's operational efficiency and debt service capacity. By focusing on this relationship, the signal aims to reflect aspects of cash flow management and financial sustainability in a manner that is both scalable and inter-

pretable. We construct this ratio using end-of-fiscal-year values for both AOLOCH and XINT to ensure consistency and comparability across firms and over time.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the GIEM signal. Panel A plots the time-series of the mean, median, and interquartile range for GIEM. On average, the cross-sectional mean (median) GIEM is 2.12 (-0.03) over the 1989 to 2023 sample, where the starting date is determined by the availability of the input GIEM data. The signal’s interquartile range spans -1.70 to 1.48. Panel B of Figure 1 plots the time-series of the coverage of the GIEM signal for the CRSP universe. On average, the GIEM signal is available for 5.97% of CRSP names, which on average make up 7.41% of total market capitalization.

4 Does GIEM predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on GIEM using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high GIEM portfolio and sells the low GIEM portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short GIEM strategy earns an average return of 0.23% per month with a t-statistic of 2.62. The annualized Sharpe ratio of the strategy is 0.45. The alphas range from 0.21% to 0.28% per month and have t-statistics exceeding 2.45 everywhere. The lowest alpha is with respect to

the FF4 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is 0.08, with a t-statistic of 3.91 on the UMD factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 537 stocks and an average market capitalization of at least \$2,303 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 21 bps/month with a t-statistics of 3.40. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-five exceed two, and for ten exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient

portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 0-36bps/month. The lowest return, (0 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of 0.05. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the GIEM trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-two cases, and significantly expands the achievable frontier in twenty cases.

Table 3 provides direct tests for the role size plays in the GIEM strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and GIEM, as well as average returns and alphas for long/short trading GIEM strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the GIEM strategy achieves an average return of 35 bps/month with a t-statistic of 3.14. Among these large cap stocks, the alphas for the GIEM strategy relative to the five most common factor models range from 30 to 41 bps/month with t-statistics between 2.70 and 3.55.

5 How does GIEM perform relative to the zoo?

Figure 2 puts the performance of GIEM in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212

documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the GIEM strategy falls in the distribution. The GIEM strategy’s gross (net) Sharpe ratio of 0.45 (0.40) is greater than 87% (97%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the GIEM strategy (red line).² Ignoring trading costs, a \$1 invested in the GIEM strategy would have yielded \$1.31 which ranks the GIEM strategy in the top 5% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the GIEM strategy would have yielded \$1.10 which ranks the GIEM strategy in the top 5% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the GIEM relative to those. Panel A shows that the GIEM strategy gross alphas fall between the 49 and 75 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 198906 to 202306 sample. For example, 45% (53%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The GIEM strategy has a positive net generalized alpha for five out of the five factor models. In these cases GIEM ranks between the 68 and 87 percentiles in terms of how much it could have expanded the achievable investment frontier.

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

6 Does GIEM add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of GIEM with 209 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price GIEM or at least to weaken the power GIEM has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of GIEM conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{GIEM} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{GIEM}GIEM_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{GIEM,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on GIEM. Stocks are finally grouped into five GIEM portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

GIEM trading strategies conditioned on each of the 209 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on GIEM and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the GIEM signal in these Fama-MacBeth regressions exceed 1.48, with the minimum t-statistic occurring when controlling for Book-to-market and accruals. Controlling for all six closely related anomalies, the t-statistic on GIEM is 0.42.

Similarly, Table 5 reports results from spanning tests that regress returns to the GIEM strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the GIEM strategy earns alphas that range from 18-23bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.07, which is achieved when controlling for Book-to-market and accruals. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the GIEM trading strategy achieves an alpha of 20bps/month with a t-statistic of 2.36.

7 Does GIEM add relative to the whole zoo?

Finally, we can ask how much adding GIEM to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 159 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 159 anomalies augmented with the GIEM signal.⁴ We consider

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capital-

one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 159-anomaly combination strategy grows to \$42.41, while \$1 investment in the combination strategy that includes GIEM grows to \$40.48.

8 Conclusion

This study provides compelling evidence for the effectiveness of the Growth Impact Efficiency Metric (GIEM) as a significant predictor of stock returns in the cross-section of equities. Our findings demonstrate that a value-weighted long/short trading strategy based on GIEM generates economically and statistically significant returns, with impressive Sharpe ratios of 0.45 and 0.40 for gross and net returns, respectively. The strategy’s robustness is particularly noteworthy, maintaining significant abnormal returns even after controlling for traditional risk factors and related anomalies.

The persistence of GIEM’s predictive power, evidenced by monthly alphas of 24 basis points (gross) and 21 basis points (net) relative to the Fama-French five-factor model plus momentum, suggests that this signal captures unique information not fully reflected in existing factor models. Furthermore, the signal’s ability to generate a significant alpha of 20 basis points per month even after controlling for six closely related anomalies underscores its distinctive contribution to the cross-sectional prediction of stock returns.

However, several limitations should be noted. First, our analysis focuses on U.S.

ization on CRSP in the period for which GIEM is available.

equity markets, and the signal’s effectiveness in international markets remains to be tested. Second, transaction costs and market impact could affect the strategy’s real-world implementation, particularly for smaller stocks or during periods of market stress.

Future research could explore several promising directions. First, investigating the signal’s performance in international markets would help establish its global applicability. Second, examining the interaction between GIEM and other established anomalies could yield insights into potential complementarities or substitution effects. Finally, studying the signal’s behavior during different market regimes and economic conditions could provide valuable insights for practical implementation.

In conclusion, GIEM represents a valuable addition to the arsenal of quantitative signals for predicting stock returns, offering robust performance even after accounting for transaction costs and controlling for related factors. These findings have important implications for both academic research in asset pricing and practical applications in investment management.

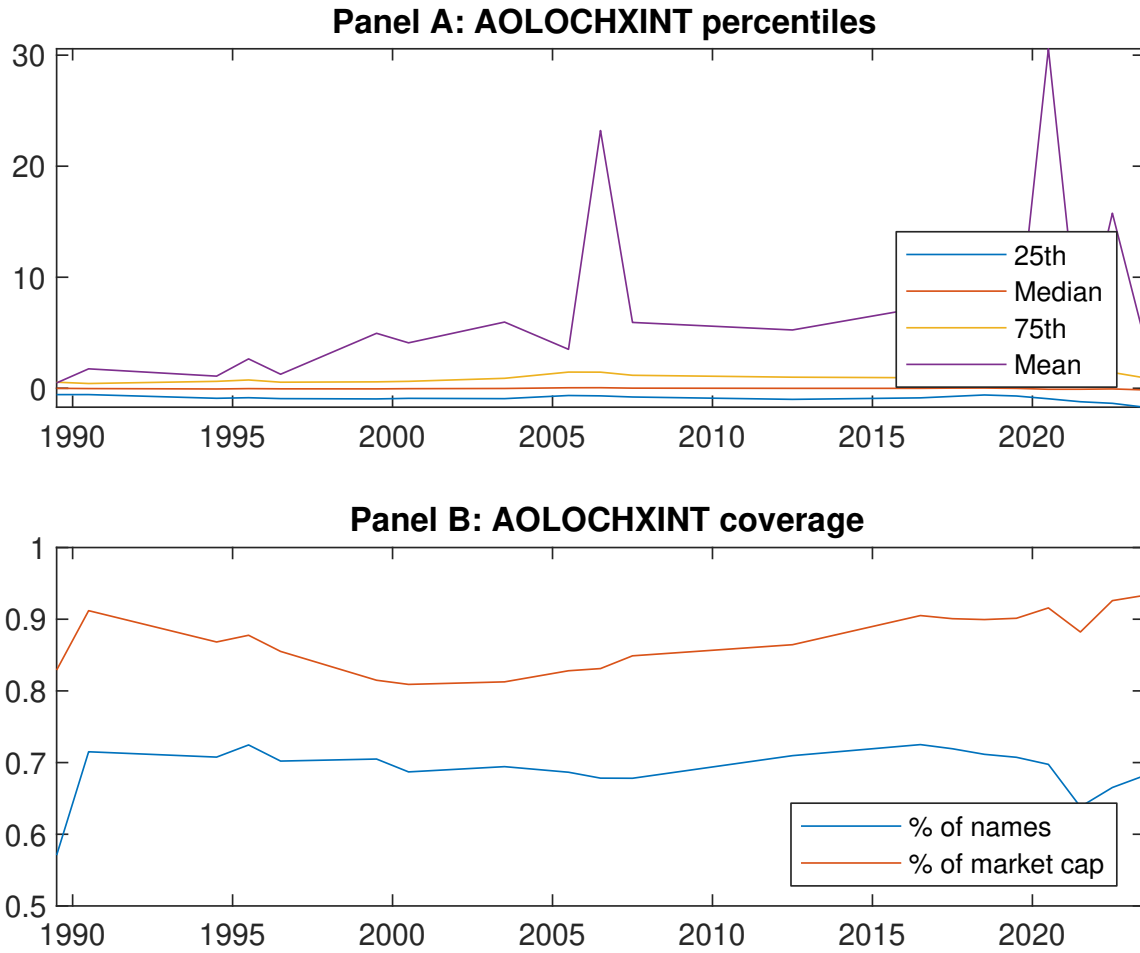

Figure 1: Times series of GIEM percentiles and coverage.
This figure plots descriptive statistics for GIEM. Panel A shows cross-sectional percentiles of GIEM over the sample. Panel B plots the monthly coverage of GIEM relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on GIEM. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 198906 to 202306.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the GIEM strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 198906 to 202306.

Panel A: Gross Returns and Alphas

Table 3: Conditional sort on size and GIEM

This table presents results for conditional double sorts on size and GIEM. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on GIEM. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high GIEM and short stocks with low GIEM. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 198906 to 202306.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	GIEM Quintiles					GIEM Strategies						
		(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the GIEM with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the GIEM trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 4: Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the GIEM trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, [Fama and French \(1993\)](#) three-factor model, [Fama and French \(1993\)](#) three-factor model augmented with the [Carhart \(1997\)](#) momentum factor, [Fama and French \(2015\)](#) five-factor model, and the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor following [Fama and French \(2018\)](#). The left panel plots alphas with no adjustment for trading costs. The right panel plots [Novy-Marx and Velikov \(2016\)](#) net generalized alphas.

Figure 5: Distribution of correlations. This figure plots a name histogram of correlations of 209 filtered anomaly signals with GIEM. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of GIEM conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{GIEM} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{GIEM} GIEM_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{GIEM,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 209 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on GIEM. Stocks are finally grouped into five GIEM portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted GIEM trading strategies conditioned on each of the 209 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on GIEM. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{GIEM}GIEM_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Change in current operating liabilities, Total accruals, Book-to-market and accruals, Efficient frontier index, Change in Taxes, Price. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 198906 to 202306.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the GIEM trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{GIEM} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Change in current operating liabilities, Total accruals, Book-to-market and accruals, Efficient frontier index, Change in Taxes, Price. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 198906 to 202306.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 159 anomalies. The red solid lines indicate combination trading strategies that utilize the 159 anomalies as well as GIEM. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
