

# Stock Equity Imbalance Scale and the Cross Section of Stock Returns

I. M. Harking

December 1, 2024

## Abstract

This paper studies the asset pricing implications of Stock Equity Imbalance Scale (SEIS), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on SEIS achieves an annualized gross (net) Sharpe ratio of 0.58 (0.51), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 23 (23) bps/month with a t-statistic of 2.91 (2.93), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth) is 19 bps/month with a t-statistic of 2.51.

# 1 Introduction

Market efficiency remains a central question in asset pricing, with researchers continually seeking to identify reliable signals that predict cross-sectional stock returns. While numerous return predictors have been documented in the literature, many fail to survive transaction costs or are subsumed by known factors (Harvey et al., 2016). The challenge lies not just in discovering new signals, but in identifying those that are both economically meaningful and robust to trading frictions.

Despite extensive research on equity issuance and capital structure decisions, the literature has paid limited attention to how firms' relative changes in equity capital signal future returns. While studies have examined absolute changes in shares outstanding (Pontiff and Woodgate, 2008) and total asset growth (Cooper et al., 2008), the scaled imbalance between equity changes and existing capital structure may contain unique information about managerial expectations and future firm performance.

We propose that the Stock Equity Imbalance Scale (SEIS) captures managers' private information about future prospects through their decisions to adjust equity capital relative to existing capital structure. Building on the market timing hypothesis of Baker and Wurgler (2002), managers are more likely to issue equity when they believe shares are overvalued and repurchase when undervalued. The SEIS measure refines this insight by scaling equity changes against the firm's existing capital structure.

The theoretical mechanism operates through two channels. First, following Myers (1984)'s pecking order theory, firms prefer internal financing to external equity. Therefore, substantial equity issuance relative to existing capital may signal that managers have exhausted internal resources and face poor future prospects. Second, as argued by Loughran and Ritter (1995), firms time equity issuance to exploit overvaluation, making large relative increases in equity a negative signal.

Conversely, stock repurchases represent a positive signal when scaled by existing

capital. As demonstrated by [Ikenberry et al. \(1995\)](#), repurchases often indicate managerial beliefs that shares are undervalued. The SEIS measure captures this effect while controlling for firm size through scaling, potentially yielding a more precise signal of managerial private information.

Our empirical analysis reveals that SEIS strongly predicts future stock returns. A value-weighted long-short strategy based on SEIS quintiles generates a monthly alpha of 23 basis points (t-statistic = 2.91) relative to the Fama-French six-factor model. The strategy achieves an impressive annualized Sharpe ratio of 0.58 before trading costs and 0.51 after accounting for transaction costs.

The predictive power of SEIS remains robust across various methodological specifications. The signal maintains significance when controlling for size, with the long-short strategy earning a monthly alpha of 26 basis points (t-statistic = 2.79) among the largest quintile of stocks. This indicates that the effect is not driven by small, illiquid stocks.

Most importantly, SEIS continues to predict returns even after controlling for related anomalies. When we simultaneously control for the six most closely related predictors including share issuance and asset growth, SEIS generates a monthly alpha of 19 basis points (t-statistic = 2.51). This suggests that SEIS captures unique information not contained in existing equity-based signals.

Our study makes several contributions to the asset pricing literature. First, we introduce a novel predictor that captures managerial private information through scaled equity decisions, extending work by [Pontiff and Woodgate \(2008\)](#) and [Cooper et al. \(2008\)](#) on equity issuance and asset growth. The scaling approach provides a more precise measure of managers' capital structure decisions relative to firm size.

Second, we demonstrate robust predictability that survives stringent controls and transaction costs, addressing concerns raised by [McLean et al. \(2009\)](#) about the implementability of equity-based trading strategies. Our findings are particularly no-

table given that SEIS predicts returns even among large, liquid stocks where trading frictions are lower.

Finally, our results contribute to the broader literature on market efficiency and the information content of managerial decisions. The persistence of SEIS predictability, even after controlling for known factors and related anomalies, suggests that markets do not fully incorporate the information contained in scaled equity changes. This finding has important implications for both academic research on market efficiency and practical applications in investment management.

## 2 Data

Our study investigates the predictive power of Stock Equity Imbalance Scale, a financial signal derived from accounting data for cross-sectional returns. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT's item CSTK for common stock and item SEQ for stockholders' equity. Common stock (CSTK) represents the par value of all outstanding common shares, while stockholders' equity (SEQ) represents the total equity investment by shareholders in the company, including retained earnings and other comprehensive income. Construction of the signal follows a difference-to-scale format, where we calculate the year-over-year change in CSTK and normalize it by the previous year's SEQ. Specifically, for each firm in each year, we subtract the previous year's CSTK from the current year's CSTK and divide this difference by the previous year's SEQ. This scaled difference captures the relative magnitude of changes in common stock relative to the firm's existing equity base, potentially indicating significant equity issuance or repurchase activities. By scaling the change in common stock by lagged stockholders' equity, we ensure comparability across firms of different sizes and control for the overall scale of

equity financing. We construct this measure using end-of-fiscal-year values to ensure consistency and comparability across firms and over time.

### 3 Signal diagnostics

Figure 1 plots descriptive statistics for the SEIS signal. Panel A plots the time-series of the mean, median, and interquartile range for SEIS. On average, the cross-sectional mean (median) SEIS is -0.02 (-0.00) over the 1966 to 2023 sample, where the starting date is determined by the availability of the input SEIS data. The signal's interquartile range spans -0.01 to 0.00. Panel B of Figure 1 plots the time-series of the coverage of the SEIS signal for the CRSP universe. On average, the SEIS signal is available for 6.63% of CRSP names, which on average make up 7.96% of total market capitalization.

### 4 Does SEIS predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on SEIS using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high SEIS portfolio and sells the low SEIS portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short SEIS strategy earns an average return of 0.34% per month with a t-statistic of 4.37. The annualized Sharpe ratio of the strategy is 0.58. The alphas range from 0.23% to 0.36% per month and have t-statistics exceeding 2.91 everywhere. The lowest alpha is with

respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is 0.30, with a t-statistic of 5.66 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 614 stocks and an average market capitalization of at least \$1,477 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using cap breakpoints and value-weighted portfolios, and equals 30 bps/month with a t-statistics of 3.91. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-five exceed two, and for nineteen exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient

portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 27-31bps/month. The lowest return, (27 bps/month), is achieved from the quintile sort using cap breakpoints and value-weighted portfolios, and has an associated t-statistic of 3.45. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the SEIS trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in twenty-five cases.

Table 3 provides direct tests for the role size plays in the SEIS strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and SEIS, as well as average returns and alphas for long/short trading SEIS strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80<sup>th</sup> NYSE percentile), the SEIS strategy achieves an average return of 26 bps/month with a t-statistic of 2.79. Among these large cap stocks, the alphas for the SEIS strategy relative to the five most common factor models range from 20 to 26 bps/month with t-statistics between 2.02 and 2.73.

## 5 How does SEIS perform relative to the zoo?

Figure 2 puts the performance of SEIS in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212

documented anomalies in the zoo.<sup>1</sup> The vertical red line shows where the Sharpe ratio for the SEIS strategy falls in the distribution. The SEIS strategy’s gross (net) Sharpe ratio of 0.58 (0.51) is greater than 95% (99%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the SEIS strategy (red line).<sup>2</sup> Ignoring trading costs, a \$1 invested in the SEIS strategy would have yielded \$8.36 which ranks the SEIS strategy in the top 1% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the SEIS strategy would have yielded \$6.25 which ranks the SEIS strategy in the top 0% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the SEIS relative to those. Panel A shows that the SEIS strategy gross alphas fall between the 69 and 74 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196606 to 202306 sample. For example, 45% (53%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The SEIS strategy has a positive net generalized alpha for five out of the five factor models. In these cases SEIS ranks between the 84 and 91 percentiles in terms of how much it could have expanded the achievable investment frontier.

---

<sup>1</sup>The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

<sup>2</sup>The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

## 6 Does SEIS add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of SEIS with 210 filtered anomaly signals.<sup>3</sup> Figure 6 also shows an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price SEIS or at least to weaken the power SEIS has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of SEIS conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on  $\beta_{SEIS}$  from Fama-MacBeth regressions of the form  $r_{i,t} = \alpha + \beta_{SEIS}SEIS_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$ , where  $X$  stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on  $\alpha$  from spanning tests of the form:  $r_{SEIS,t} = \alpha + \beta r_{X,t} + \epsilon_t$ , where  $r_{X,t}$  stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on SEIS. Stocks are finally grouped into five SEIS portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted

---

<sup>3</sup>When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

SEIS trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on SEIS and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the SEIS signal in these Fama-MacBeth regressions exceed 2.88, with the minimum t-statistic occurring when controlling for Net Payout Yield. Controlling for all six closely related anomalies, the t-statistic on SEIS is 2.11.

Similarly, Table 5 reports results from spanning tests that regress returns to the SEIS strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the SEIS strategy earns alphas that range from 20-25bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.57, which is achieved when controlling for Net Payout Yield. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the SEIS trading strategy achieves an alpha of 19bps/month with a t-statistic of 2.51.

## 7 Does SEIS add relative to the whole zoo?

Finally, we can ask how much adding SEIS to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the SEIS signal.<sup>4</sup> We consider one different methods for combining signals.

---

<sup>4</sup>We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which SEIS is available.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$2333.55, while \$1 investment in the combination strategy that includes SEIS grows to \$2303.03.

## 8 Conclusion

This study provides compelling evidence for the effectiveness of the Stock Equity Imbalance Scale (SEIS) as a robust predictor of cross-sectional stock returns. Our findings demonstrate that SEIS-based trading strategies yield economically and statistically significant results, with a value-weighted long/short strategy achieving impressive Sharpe ratios of 0.58 (gross) and 0.51 (net). The strategy’s persistence in generating significant abnormal returns, even after controlling for the Fama-French five factors plus momentum (23 bps/month), and its continued significance when accounting for six closely related factor strategies (19 bps/month), underscores SEIS’s unique contribution to return prediction.

The results are particularly noteworthy as they maintain their significance even after accounting for transaction costs, suggesting practical implementability for institutional investors. The signal’s robustness across various control specifications indicates that SEIS captures distinct information about future stock returns that is not fully explained by traditional factors or related anomalies.

However, several limitations should be noted. First, our analysis focuses primarily on U.S. equity markets, and the signal’s effectiveness in international markets remains to be tested. Second, the study period may not fully capture the signal’s behavior

during extreme market conditions.

Future research could explore the application of SEIS in international markets, investigate its interaction with other market anomalies, and examine its performance during different market regimes. Additionally, researchers might investigate the underlying economic mechanisms driving the SEIS effect and its potential implications for market efficiency theories. Understanding these aspects would further enhance our knowledge of equity market dynamics and potentially lead to more refined investment strategies.

**Figure 1:** Times series of SEIS percentiles and coverage. This figure plots descriptive statistics for SEIS. Panel A shows cross-sectional percentiles of SEIS over the sample. Panel B plots the monthly coverage of SEIS relative to the universe of CRSP stocks with available market capitalizations.

**Table 1:** Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on SEIS. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196606 to 202306.

**Table 2:** Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the SEIS strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196606 to 202306.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	$r^e$	$\alpha_{\text{CAPM}}$	$\alpha_{\text{FF3}}$	$\alpha_{\text{FF4}}$	$\alpha_{\text{FF5}}$	$\alpha_{\text{FF6}}$

**Table 3:** Conditional sort on size and SEIS

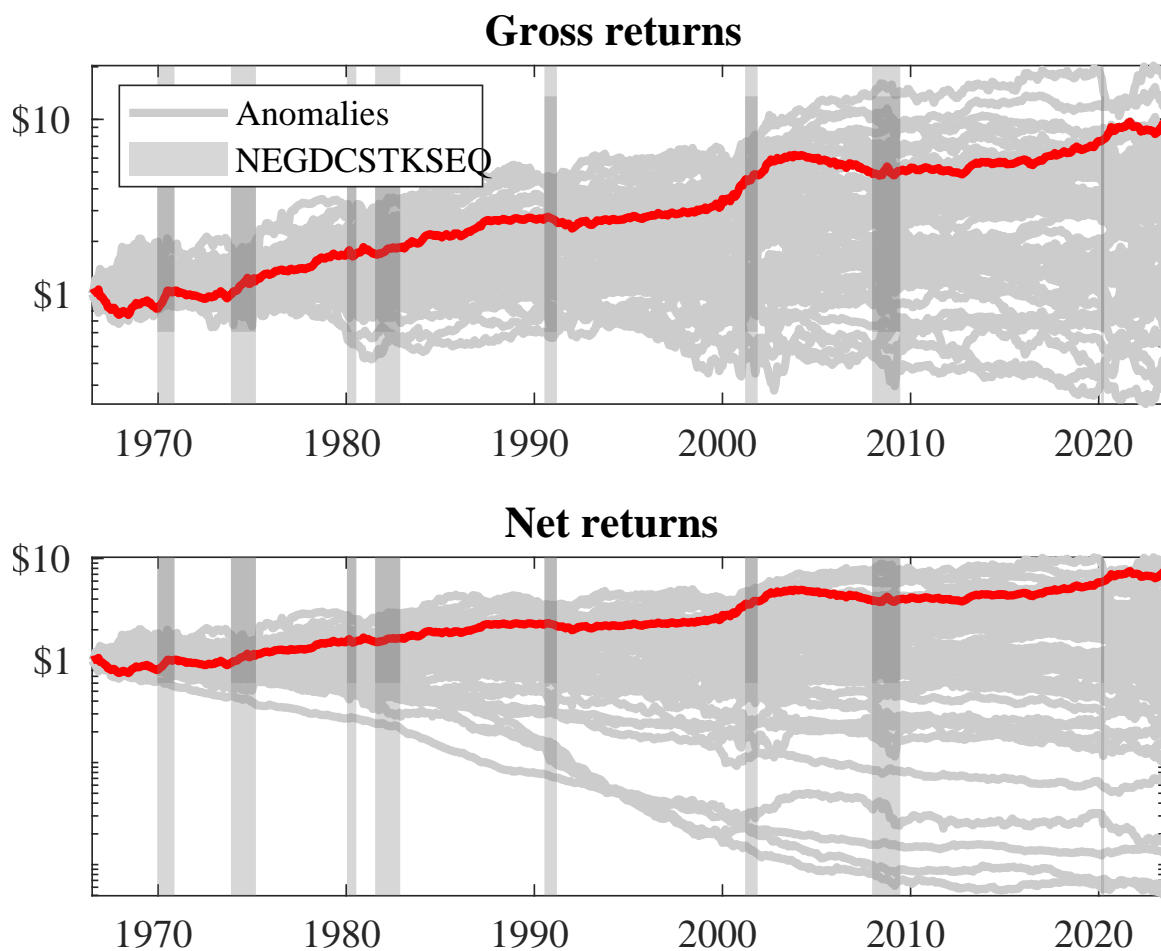

This table presents results for conditional double sorts on size and SEIS. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on SEIS. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high SEIS and short stocks with low SEIS. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 196606 to 202306.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	SEIS Quintiles					SEIS Strategies

**Figure 2:** Distribution of Sharpe ratios.  
This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the SEIS with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

**Figure 3:** Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the SEIS trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

**Figure 4:** Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the SEIS trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). The left panel plots alphas with no adjustment for trading costs. The right panel plots Novy-Marx and Velikov (2016) net generalized alphas.

**Figure 5:** Distribution of correlations. This figure plots a name histogram of correlations of 210 filtered anomaly signals with SEIS. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

**Figure 6:** Agglomerative hierarchical cluster plot

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

**Figure 7:** Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of SEIS conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on  $\beta_{SEIS}$  from Fama-MacBeth regressions of the form  $r_{i,t} = \alpha + \beta_{SEIS}SEIS_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$ , where  $X$  stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on  $\alpha$  from spanning tests of the form:  $r_{SEIS,t} = \alpha + \beta r_{X,t} + \epsilon_t$ , where  $r_{X,t}$  stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on SEIS. Stocks are finally grouped into five SEIS portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted SEIS trading strategies conditioned on each of the 210 filtered anomalies.

**Table 4:** Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on SEIS. and the six most closely related anomalies. The regressions take the following form:  $r_{i,t} = \alpha + \beta_{SEIS}SEIS_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$ . The six most closely related anomalies,  $X$ , are Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

**Table 5:** Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the SEIS trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form:  $r_t^{SEIS} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$ , where  $X_k$  indicates each of the six most-closely related anomalies and  $f_j$  indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies,  $X$ , are Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

**Figure 8:** Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as SEIS. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
