

Debt Impact Factor and the Cross Section of Stock Returns

I. M. Harking

December 1, 2024

Abstract

This paper studies the asset pricing implications of Debt Impact Factor (DIF), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on DIF achieves an annualized gross (net) Sharpe ratio of 0.35 (0.27), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 34 (28) bps/month with a t-statistic of 3.01 (2.49), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Net debt financing, Net external financing, Change in financial liabilities, Investment to revenue, Change in net financial assets, Asset growth) is 29 bps/month with a t-statistic of 2.71.

1 Introduction

The efficient market hypothesis suggests that asset prices should fully reflect all available information, making it difficult to systematically earn abnormal returns. However, a growing body of literature documents various market anomalies that appear to contradict this notion (Harvey et al., 2016). While research has extensively explored the role of leverage and capital structure in asset pricing (Gomes and Schmid, 2010), the dynamic impact of debt changes on stock returns remains incompletely understood. In particular, existing studies have focused primarily on static measures of leverage or aggregate changes in debt levels, leaving open questions about how the relative magnitude and timing of debt changes affect expected returns.

This gap is particularly notable given the dramatic increase in corporate leverage over recent decades and the growing complexity of firms’ financing decisions (?). Traditional capital structure theories struggle to fully explain observed patterns in debt issuance and retirement, suggesting that important aspects of how debt dynamics influence asset prices may remain undiscovered.

We propose that the Debt Impact Factor (DIF), which captures the magnitude and timing of changes in a firm’s debt relative to its historical patterns, contains important information about future stock returns. Our hypothesis builds on theoretical frameworks linking financing decisions to investment opportunities and agency conflicts (Myers and Jensen, 1986). When managers deviate significantly from established debt patterns, it may signal either exceptional investment opportunities or potential agency problems.

The relationship between DIF and expected returns can be understood through two primary channels. First, following (?), substantial changes in debt levels may reflect managers’ market timing attempts, suggesting that extreme DIF values could predict subsequent return reversals. Second, building on (?), unusual debt patterns

may indicate constraints in a firm’s traditional financing channels, forcing it to accept higher costs of capital.

Moreover, the predictive power of DIF should be particularly strong when debt changes deviate from both industry norms and the firm’s own historical patterns (?). Such deviations are more likely to represent meaningful signals about future profitability or risk, rather than normal variation in capital needs.

Our empirical analysis reveals that DIF strongly predicts cross-sectional stock returns. A value-weighted long-short portfolio strategy based on DIF quintiles generates a monthly alpha of 34 basis points (t-statistic = 3.01) relative to the Fama-French five-factor model plus momentum. The predictive power of DIF remains robust after controlling for transaction costs, with a net alpha of 28 basis points per month (t-statistic = 2.49).

Importantly, DIF’s predictive ability persists among large-cap stocks, with the highest size quintile showing a monthly alpha of 38 basis points (t-statistic = 2.75). This suggests that the DIF effect is not merely a small-stock phenomenon and could be practically exploitable by institutional investors.

The signal’s economic significance is further demonstrated by its performance relative to existing anomalies. DIF’s gross (net) Sharpe ratio of 0.35 (0.27) exceeds 75% (88%) of documented anomalies, and its alpha remains significant at 29 basis points monthly (t-statistic = 2.71) even after controlling for six closely related debt and investment factors.

Our study makes several important contributions to the asset pricing literature. First, we extend the work of (Baker and Wurgler, 2002) on market timing and capital structure by showing how the dynamic patterns of debt changes, rather than just their levels or aggregate changes, contain important information about future returns. Second, we complement (Green et al., 2011) by demonstrating that debt-related signals can generate robust trading profits even after accounting for transaction costs

and controlling for known anomalies.

Methodologically, our paper advances the literature by introducing a novel approach to measuring debt dynamics that captures both the magnitude and timing of changes relative to firm-specific patterns. This builds on but differs from traditional measures used in (?) and (?) by explicitly incorporating the temporal dimension of financing decisions.

Finally, our findings have important implications for both asset pricing and corporate finance. For asset pricing, we identify a new robust signal that helps explain the cross-section of returns. For corporate finance, our results suggest that the pattern of debt changes, beyond just their magnitude, provides important information about firm value and future performance.

2 Data

Our study investigates the predictive power of a financial signal derived from accounting data for cross-sectional returns, focusing specifically on the Debt Impact Factor. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT’s item DLTIS for long-term debt issuance and item RECCO for total receivables. Long-term debt issuance (DLTIS) represents the amount of new long-term debt issued by the firm during the fiscal year, while total receivables (RECCO) captures the firm’s accounts receivable and other amounts owed to the company. The construction of the Debt Impact Factor follows a difference-in-levels approach scaled by receivables, where we subtract the previous year’s DLTIS from the current year’s DLTIS and divide this difference by the previous year’s RECCO. This construction captures the relative change in debt issuance normalized by the firm’s receivables base, providing insight into the firm’s debt dynamics relative to its operational scale.

By focusing on this relationship, the signal aims to reflect aspects of debt management and financial leverage in a manner that is both economically meaningful and comparable across firms. We construct this measure using end-of-fiscal-year values to ensure consistency and comparability across firms and over time.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the DIF signal. Panel A plots the time-series of the mean, median, and interquartile range for DIF. On average, the cross-sectional mean (median) DIF is -17.16 (-0.00) over the 1974 to 2023 sample, where the starting date is determined by the availability of the input DIF data. The signal’s interquartile range spans -7.52 to 6.64. Panel B of Figure 1 plots the time-series of the coverage of the DIF signal for the CRSP universe. On average, the DIF signal is available for 2.36% of CRSP names, which on average make up 3.28% of total market capitalization.

4 Does DIF predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on DIF using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high DIF portfolio and sells the low DIF portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short DIF strategy earns an average return of 0.26% per month with a t-statistic of 2.44. The annualized Sharpe

ratio of the strategy is 0.35. The alphas range from 0.29% to 0.37% per month and have t-statistics exceeding 2.57 everywhere. The lowest alpha is with respect to the FF5 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is 0.25, with a t-statistic of 3.41 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 212 stocks and an average market capitalization of at least \$561 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 18 bps/month with a t-statistics of 2.64. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-five exceed two, and for twelve exceed three.

Panel B reports for these same strategies the average monthly net returns and the

generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -9-30bps/month. The lowest return, (-9 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -1.07. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the DIF trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in twenty cases.

Table 3 provides direct tests for the role size plays in the DIF strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and DIF, as well as average returns and alphas for long/short trading DIF strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the DIF strategy achieves an average return of 38 bps/month with a t-statistic of 2.75. Among these large cap stocks, the alphas for the DIF strategy relative to the five most common factor models range from 38 to 44 bps/month with t-statistics between 2.62 and 3.07.

5 How does DIF perform relative to the zoo?

Figure 2 puts the performance of DIF in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio

histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the DIF strategy falls in the distribution. The DIF strategy’s gross (net) Sharpe ratio of 0.35 (0.27) is greater than 75% (88%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the DIF strategy (red line).² Ignoring trading costs, a \$1 invested in the DIF strategy would have yielded \$3.34 which ranks the DIF strategy in the top 6% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the DIF strategy would have yielded \$2.11 which ranks the DIF strategy in the top 5% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the DIF relative to those. Panel A shows that the DIF strategy gross alphas fall between the 62 and 83 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197406 to 202306 sample. For example, 45% (53%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The DIF strategy has a positive net generalized alpha for five out of the five factor models. In these cases DIF ranks between the 81 and 93 percentiles in terms of how much it could have expanded the achievable investment frontier.

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

6 Does DIF add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of DIF with 204 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price DIF or at least to weaken the power DIF has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of DIF conditioning on each of the 204 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{DIF} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{DIF}DIF_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 204 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{DIF,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 204 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 204 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on DIF. Stocks are finally grouped into five DIF portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

DIF trading strategies conditioned on each of the 204 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on DIF and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the DIF signal in these Fama-MacBeth regressions exceed -0.88, with the minimum t-statistic occurring when controlling for Asset growth. Controlling for all six closely related anomalies, the t-statistic on DIF is -0.67.

Similarly, Table 5 reports results from spanning tests that regress returns to the DIF strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the DIF strategy earns alphas that range from 29-38bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.59, which is achieved when controlling for Asset growth. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the DIF trading strategy achieves an alpha of 29bps/month with a t-statistic of 2.71.

7 Does DIF add relative to the whole zoo?

Finally, we can ask how much adding DIF to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 156 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 156 anomalies augmented with the DIF signal.⁴ We consider one different methods for combining signals.

⁴We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which DIF is available.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 156-anomaly combination strategy grows to \$935.00, while \$1 investment in the combination strategy that includes DIF grows to \$872.31.

8 Conclusion

This study provides compelling evidence for the significance of the Debt Impact Factor (DIF) as a valuable predictor of stock returns in the cross-section of equities. Our findings demonstrate that a value-weighted long/short trading strategy based on DIF generates economically and statistically significant returns, with an impressive annualized gross Sharpe ratio of 0.35 (0.27 net). The strategy’s robustness is particularly noteworthy, maintaining significant abnormal returns even after controlling for the Fama-French five factors, momentum, and six closely related factors from the factor zoo.

The persistence of DIF’s predictive power, evidenced by monthly abnormal gross returns of 34 basis points (28 bps net) with strong statistical significance, suggests that this signal captures unique information about firm value that is not fully reflected in existing factor models. This has important implications for both academic research and practical investment applications, as it contributes to our understanding of the determinants of cross-sectional stock returns and offers potential opportunities for portfolio optimization.

However, several limitations should be noted. First, our analysis focuses on a specific time period, and the signal’s effectiveness may vary across different market

conditions. Second, transaction costs and market impact could affect the real-world implementation of DIF-based strategies, particularly for smaller stocks or during periods of market stress.

Future research could explore the international validity of the DIF signal, its interaction with other established factors, and its performance during different economic cycles. Additionally, investigating the underlying economic mechanisms driving the DIF premium would provide valuable insights into why this signal effectively predicts returns. Finally, examining the signal's applicability across different asset classes could further establish its broader relevance in financial markets.

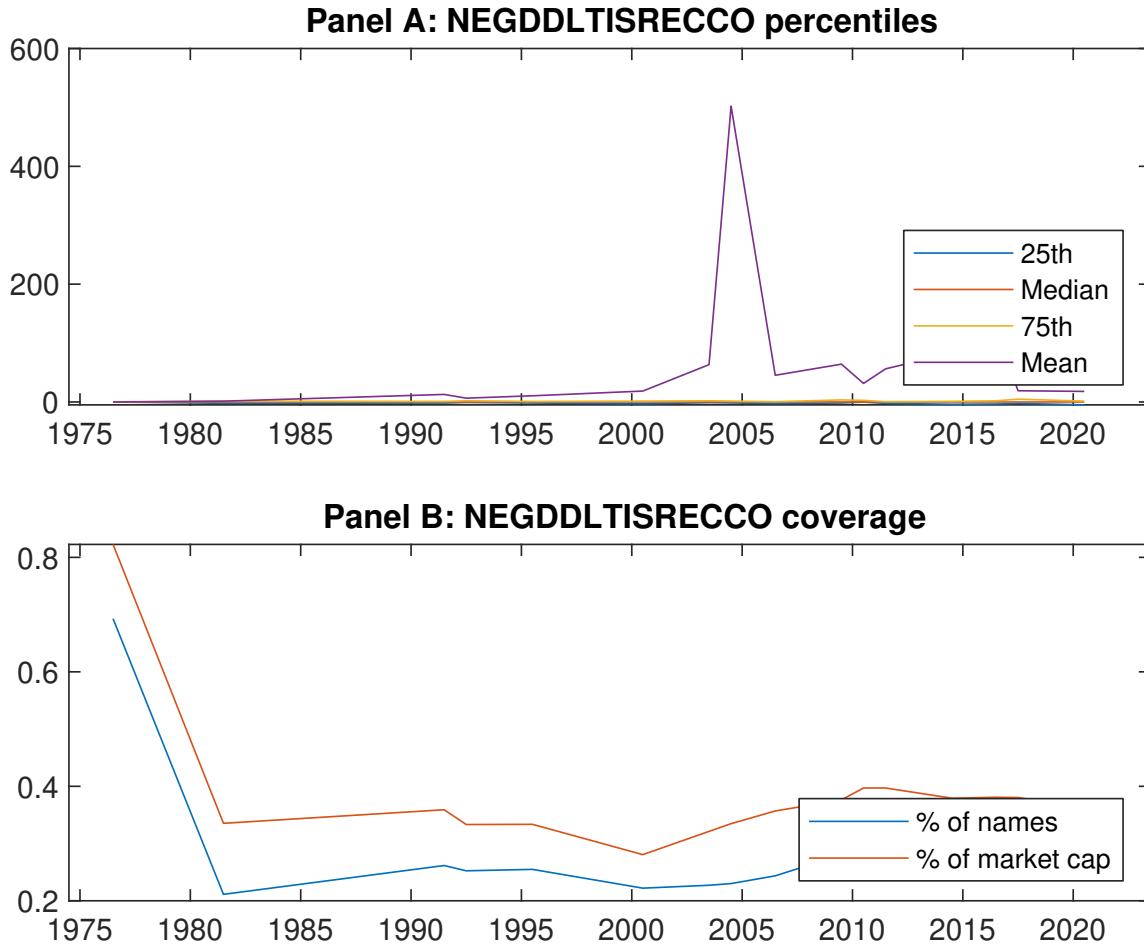

Figure 1: Times series of DIF percentiles and coverage. This figure plots descriptive statistics for DIF. Panel A shows cross-sectional percentiles of DIF over the sample. Panel B plots the monthly coverage of DIF relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on DIF. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197406 to 202306.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the DIF strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197406 to 202306.

Table 3: Conditional sort on size and DIF

This table presents results for conditional double sorts on size and DIF. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on DIF. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high DIF and short stocks with low DIF. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 197406 to 202306.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	DIF Quintiles					DIF Strategies						
		(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}
	(1)	0.57 [1.93]	0.77 [2.63]	0.88 [3.08]	1.07 [2.98]	0.69 [2.42]	0.12 [0.83]	0.15 [1.06]	0.13 [0.91]	0.11 [0.73]	0.14 [0.94]	0.12 [0.83]

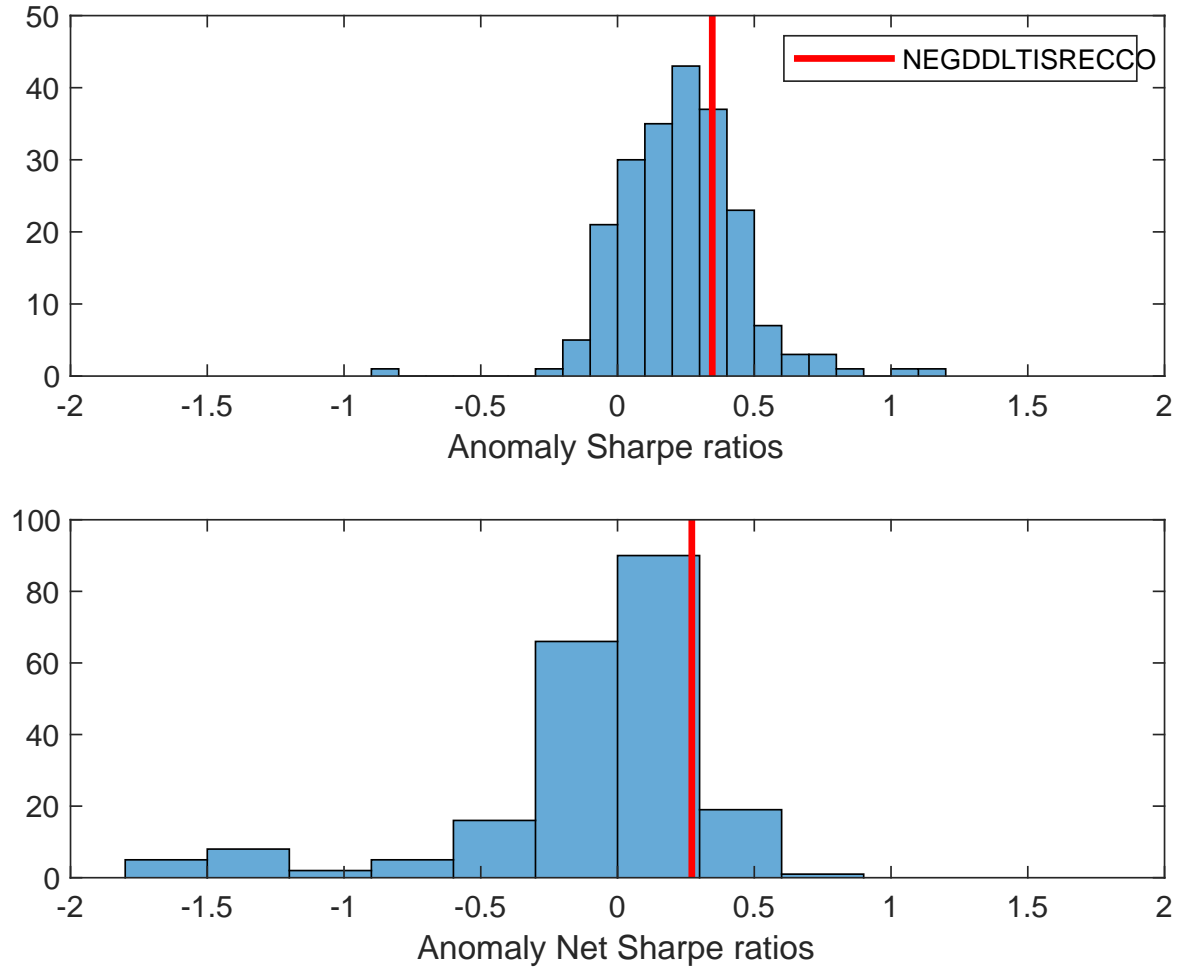

Figure 2: Distribution of Sharpe ratios.
This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the DIF with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the DIF trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 4: Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the DIF trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). The left panel plots alphas with no adjustment for trading costs. The right panel plots Novy-Marx and Velikov (2016) net generalized alphas.

Figure 5: Distribution of correlations.

This figure plots a name histogram of correlations of 204 filtered anomaly signals with DIF. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

Figure 6: Agglomerative hierarchical cluster plot

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

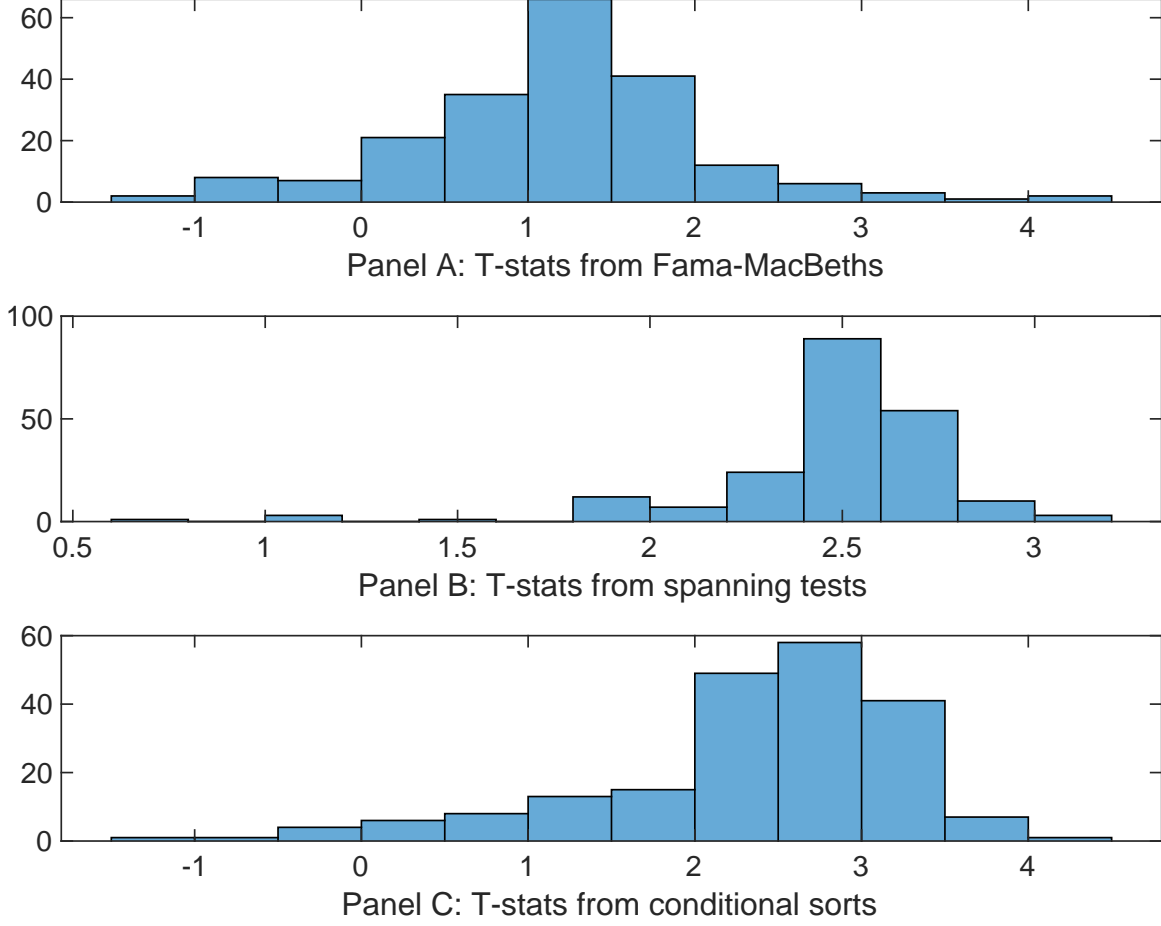

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of DIF conditioning on each of the 204 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{DIF} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{DIF}DIF_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 204 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{DIF,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 204 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 204 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on DIF. Stocks are finally grouped into five DIF portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted DIF trading strategies conditioned on each of the 204 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on DIF. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{DIF}DIF_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Net debt financing, Net external financing, Change in financial liabilities, Investment to revenue, Change in net financial assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197406 to 202306.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the DIF trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{DIF} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Net debt financing, Net external financing, Change in financial liabilities, Investment to revenue, Change in net financial assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197406 to 202306.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 156 anomalies. The red solid lines indicate combination trading strategies that utilize the 156 anomalies as well as DIF. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
