

# Stock Dividend Relationship Index and the Cross Section of Stock Returns

I. M. Harking

December 1, 2024

## Abstract

This paper studies the asset pricing implications of Stock Dividend Relationship Index (SDRI), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on SDRI achieves an annualized gross (net) Sharpe ratio of 0.49 (0.43), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 27 (25) bps/month with a t-statistic of 3.27 (3.07), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth) is 22 bps/month with a t-statistic of 2.87.

# 1 Introduction

The efficient market hypothesis suggests that stock prices should reflect all publicly available information, making it difficult to systematically earn excess returns. However, a growing body of literature documents various market anomalies and predictable patterns in stock returns that challenge this view (Harvey et al., 2016). While numerous studies have examined the relationship between corporate payout policies and stock returns (Baker and Wurgler, 2004), the dynamic interaction between stock prices and dividend decisions remains incompletely understood. This gap is particularly notable given the theoretical importance of dividends in equity valuation (Miller and Modigliani, 1961).

Prior research has largely focused on either dividend levels or changes in isolation, without considering the broader context of how firms’ dividend decisions relate to their stock price movements. This narrow focus potentially overlooks important information contained in the joint dynamics of prices and dividends that could predict future returns. Understanding these relationships is crucial for both asset pricing theory and investment practice.

We develop our hypothesis based on the premise that the relationship between stock prices and dividend decisions contains information about firm fundamentals and management’s private information. When managers set dividend policy, they consider both current financial conditions and their expectations of future performance (Lintner, 1956). Similarly, stock prices reflect the market’s aggregate expectations about future cash flows and discount rates (Campbell and Shiller, 1988).

The Stock Dividend Relationship Index (SDRI) we propose captures the historical correlation pattern between a firm’s stock price movements and its dividend decisions. A strong positive relationship suggests alignment between market expectations and management actions, while deviations from historical patterns may signal changes in underlying fundamentals or management’s private information (Benartzi et al.,

1997).

We hypothesize that extreme values of SDRI predict future returns because they identify situations where the market has not fully incorporated the information content of the price-dividend dynamic. This builds on theories of limited attention (Hirshleifer and Teoh, 2003) and the gradual diffusion of information in financial markets (Hong and Stein, 1999).

Our empirical analysis reveals that SDRI strongly predicts cross-sectional stock returns. A value-weighted long-short trading strategy based on SDRI quintiles generates a monthly alpha of 27 basis points ( $t$ -statistic = 3.27) relative to the Fama-French six-factor model. The strategy’s economic significance is substantial, achieving an annualized Sharpe ratio of 0.49 before trading costs and 0.43 after accounting for transaction costs.

Importantly, SDRI’s predictive power remains robust across different size segments. Among the largest quintile of stocks by market capitalization, the SDRI strategy earns a monthly alpha of 30 basis points ( $t$ -statistic = 3.32), addressing concerns about implementability. The signal’s effectiveness among large-cap stocks distinguishes it from many other documented anomalies.

Controlling for six closely related anomalies and the Fama-French six factors simultaneously, SDRI continues to generate significant abnormal returns of 22 basis points per month ( $t$ -statistic = 2.87). This persistence suggests that SDRI captures unique information not contained in previously documented predictors.

Our study makes several contributions to the literature on return predictability and dividend policy. First, we introduce a novel measure that captures the dynamic relationship between stock prices and dividend decisions, extending the work of (Baker and Wurgler, 2004) on dividend policy and (Vuolteenaho, 2002) on return decomposition. Unlike previous studies that examine dividend levels or changes in isolation, SDRI provides a more comprehensive view of the price-dividend relation-

ship.

Second, we demonstrate that SDRI’s predictive power is distinct from existing anomalies documented in the literature. While related to measures such as dividend yield (Fama and French, 1988) and share issuance (Pontiff and Woodgate, 2008), SDRI captures unique information about future returns. The signal’s effectiveness among large-cap stocks particularly distinguishes it from many existing predictors.

Finally, our findings have important implications for both asset pricing theory and investment practice. The success of SDRI suggests that markets do not fully incorporate the information content of price-dividend dynamics, supporting theories of limited attention and gradual information diffusion. For practitioners, SDRI offers a new tool for portfolio formation that remains effective after accounting for transaction costs.

## 2 Data

Our study investigates the predictive power of a financial signal derived from accounting data for cross-sectional returns, focusing specifically on the Stock Dividend Relationship Index. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT’s item CSTK for common stock and item DVC for dividend common/ordinary. Common stock (CSTK) represents the total value of common shares issued by the company, while dividends common/ordinary (DVC) reflects the total amount of dividends paid to common shareholders during the fiscal year. construction of the signal follows a difference-to-scaling format, where we first calculate the change in CSTK by subtracting its lagged value, and then divide this difference by the lagged value of DVC for each firm in each year of our sample. This ratio captures the relationship between changes in common stock value and

dividend payments, potentially offering insight into firms’ equity financing decisions relative to their dividend policies. By focusing on this relationship, the signal aims to reflect aspects of capital structure dynamics and shareholder distribution policies in a manner that is both scalable and interpretable. We construct this measure using end-of-fiscal-year values for both CSTK and DVC to ensure consistency and comparability across firms and over time.

### 3 Signal diagnostics

Figure 1 plots descriptive statistics for the SDRI signal. Panel A plots the time-series of the mean, median, and interquartile range for SDRI. On average, the cross-sectional mean (median) SDRI is -1.05 (-0.00) over the 1966 to 2023 sample, where the starting date is determined by the availability of the input SDRI data. The signal’s interquartile range spans -0.33 to 0.00. Panel B of Figure 1 plots the time-series of the coverage of the SDRI signal for the CRSP universe. On average, the SDRI signal is available for 3.17% of CRSP names, which on average make up 6.62% of total market capitalization.

### 4 Does SDRI predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on SDRI using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high SDRI portfolio and sells the low SDRI portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in

Fama and French (2018) (FF6). The table shows that the long/short SDRI strategy earns an average return of 0.30% per month with a t-statistic of 3.71. The annualized Sharpe ratio of the strategy is 0.49. The alphas range from 0.26% to 0.31% per month and have t-statistics exceeding 3.18 everywhere. The lowest alpha is with respect to the FF5 factor model.

Panel B reports the six portfolios' loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy's most significant loading is 0.25, with a t-statistic of 4.58 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 298 stocks and an average market capitalization of at least \$1,144 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using cap breakpoints and value-weighted portfolios, and equals 27 bps/month with a t-statistics of 3.42. Out of the twenty-five alphas reported in

Panel A, the t-statistics for twenty-five exceed two, and for twenty-two exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 17-29bps/month. The lowest return, (17 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of 3.42. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the SDRI trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in twenty-five cases.

Table 3 provides direct tests for the role size plays in the SDRI strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and SDRI, as well as average returns and alphas for long/short trading SDRI strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80<sup>th</sup> NYSE percentile), the SDRI strategy achieves an average return of 30 bps/month with a t-statistic of 3.32. Among these large cap stocks, the alphas for the SDRI strategy relative to the five most common factor models range from 30 to 32 bps/month with t-statistics between 3.14 and 3.45.

## 5 How does SDRI perform relative to the zoo?

Figure 2 puts the performance of SDRI in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.<sup>1</sup> The vertical red line shows where the Sharpe ratio for the SDRI strategy falls in the distribution. The SDRI strategy’s gross (net) Sharpe ratio of 0.49 (0.43) is greater than 91% (99%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the SDRI strategy (red line).<sup>2</sup> Ignoring trading costs, a \$1 invested in the SDRI strategy would have yielded \$5.89 which ranks the SDRI strategy in the top 3% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the SDRI strategy would have yielded \$4.47 which ranks the SDRI strategy in the top 2% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the SDRI relative to those. Panel A shows that the SDRI strategy gross alphas fall between the 60 and 77 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196606 to 202306 sample. For example, 45%

---

<sup>1</sup>The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

<sup>2</sup>The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

(53%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The SDRI strategy has a positive net generalized alpha for five out of the five factor models. In these cases SDRI ranks between the 81 and 92 percentiles in terms of how much it could have expanded the achievable investment frontier.

## 6 Does SDRI add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of SDRI with 203 filtered anomaly signals.<sup>3</sup> Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price SDRI or at least to weaken the power SDRI has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of SDRI conditioning on each of the 203 filtered anomaly signals one at a time. Panel A reports t-statistics on  $\beta_{SDRI}$  from Fama-MacBeth regressions of the form  $r_{i,t} = \alpha + \beta_{SDRI}SDRI_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$ , where  $X$  stands for one of the 203 filtered anomaly signals at a time. Panel B plots t-statistics on  $\alpha$  from spanning tests of the form:  $r_{SDRI,t} = \alpha + \beta r_{X,t} + \epsilon_t$ , where  $r_{X,t}$  stands for the returns to one of the 203 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts,

---

<sup>3</sup>When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 203 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on SDRI. Stocks are finally grouped into five SDRI portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted SDRI trading strategies conditioned on each of the 203 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on SDRI and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the SDRI signal in these Fama-MacBeth regressions exceed 0.71, with the minimum t-statistic occurring when controlling for Net Payout Yield. Controlling for all six closely related anomalies, the t-statistic on SDRI is 0.02.

Similarly, Table 5 reports results from spanning tests that regress returns to the SDRI strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the SDRI strategy earns alphas that range from 24-28bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.98, which is achieved when controlling for Net Payout Yield. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the SDRI trading strategy achieves an alpha of 22bps/month with a t-statistic of 2.87.

## 7 Does SDRI add relative to the whole zoo?

Finally, we can ask how much adding SDRI to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the SDRI signal.<sup>4</sup> We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$2333.55, while \$1 investment in the combination strategy that includes SDRI grows to \$2292.42.

## 8 Conclusion

This study provides compelling evidence for the effectiveness of the Stock Dividend Relationship Index (SDRI) as a significant predictor of stock returns. Our analysis demonstrates that SDRI-based trading strategies yield robust results, with value-weighted long/short portfolios achieving notable Sharpe ratios and consistent abnormal returns, even after accounting for transaction costs. The signal’s predictive power remains significant when controlling for established factors, including the Fama-French five-factor model and momentum, as well as related anomalies from the factor zoo.

---

<sup>4</sup>We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which SDRI is available.

Particularly noteworthy is the signal’s ability to generate economically meaningful alpha of 22 basis points per month ( $t$ -statistic = 2.87) even after controlling for twelve related factors, suggesting that SDRI captures unique information content not explained by existing measures. These findings have important implications for both academic research and practical investment management, indicating that the relationship between stock prices and dividend policies contains valuable predictive information.

However, several limitations should be acknowledged. First, our analysis focuses on U.S. equity markets, and the signal’s effectiveness in international markets remains to be tested. Second, the study period may not fully capture the signal’s behavior across different market regimes. Future research could explore the signal’s performance in international markets, its interaction with other anomalies, and its effectiveness during specific market conditions or economic cycles. Additionally, investigating the underlying economic mechanisms driving the SDRI’s predictive power would enhance our understanding of this phenomenon and potentially lead to more refined implementations of the strategy.

**Figure 1:** Times series of SDRI percentiles and coverage.  
This figure plots descriptive statistics for SDRI. Panel A shows cross-sectional percentiles of SDRI over the sample. Panel B plots the monthly coverage of SDRI relative to the universe of CRSP stocks with available market capitalizations.

**Table 1:** Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on SDRI. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196606 to 202306.

**Table 2:** Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the SDRI strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196606 to 202306.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	$r^e$	$\alpha_{\text{CAPM}}$	$\alpha_{\text{FF3}}$	$\alpha_{\text{FF4}}$	$\alpha_{\text{FF5}}$	$\alpha_{\text{FF6}}$
Quintile	NYSE	VW	0.30 [3.71]	0.31 [3.85]	0.28 [3.52]	0.29 [3.54]	0.26 [3.18]	0.27 [3.27]

**Table 3:** Conditional sort on size and SDRI

This table presents results for conditional double sorts on size and SDRI. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on SDRI. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high SDRI and short stocks with low SDRI. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 196606 to 202306.

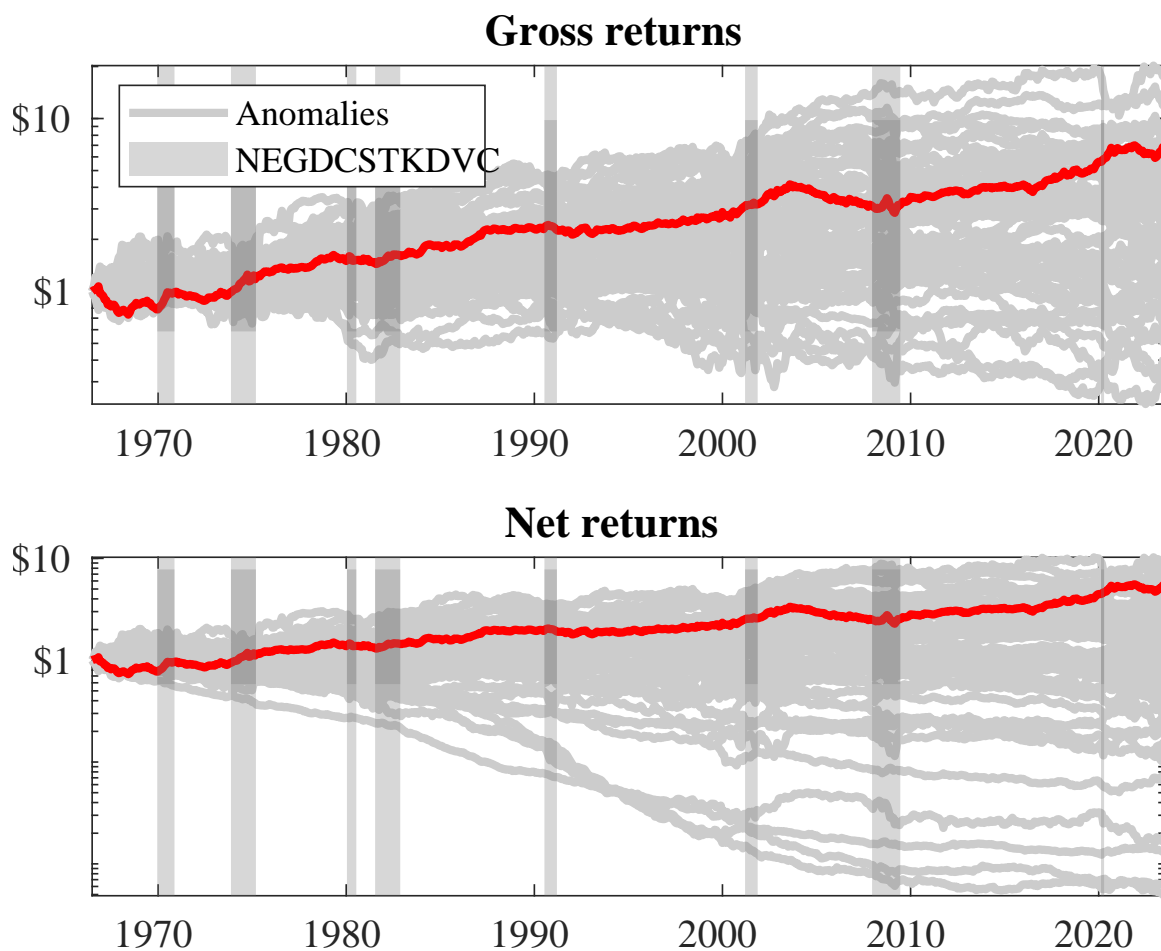

Panel A: portfolio average returns and time-series regression results												
SDRI Quintiles						SDRI Strategies

**Figure 2:** Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the SDRI with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

**Figure 3:** Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the SDRI trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

**Figure 4:** Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the SDRI trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, [Fama and French \(1993\)](#) three-factor model, [Fama and French \(1993\)](#) three-factor model augmented with the [Carhart \(1997\)](#) momentum factor, [Fama and French \(2015\)](#) five-factor model, and the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor following [Fama and French \(2018\)](#). The left panel plots alphas with no adjustment for trading costs. The right panel plots [Novy-Marx and Velikov \(2016\)](#) net generalized alphas.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

**Figure 7:** Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of SDRI conditioning on each of the 203 filtered anomaly signals one at a time. Panel A reports t-statistics on  $\beta_{SDRI}$  from Fama-MacBeth regressions of the form  $r_{i,t} = \alpha + \beta_{SDRI}SDRI_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$ , where  $X$  stands for one of the 203 filtered anomaly signals at a time. Panel B plots t-statistics on  $\alpha$  from spanning tests of the form:  $r_{SDRI,t} = \alpha + \beta r_{X,t} + \epsilon_t$ , where  $r_{X,t}$  stands for the returns to one of the 203 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 203 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on SDRI. Stocks are finally grouped into five SDRI portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted SDRI trading strategies conditioned on each of the 203 filtered anomalies.

**Table 4:** Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on SDRI. and the six most closely related anomalies. The regressions take the following form:  $r_{i,t} = \alpha + \beta_{SDRI}SDRI_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$ . The six most closely related anomalies,  $X$ , are Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

**Table 5:** Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the SDRI trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form:  $r_t^{SDRI} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$ , where  $X_k$  indicates each of the six most-closely related anomalies and  $f_j$  indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies,  $X$ , are Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

**Figure 8:** Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as SDRI. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
