

Acquisitions Efficiency Ratio and the Cross Section of Stock Returns

I. M. Harking

December 1, 2024

Abstract

This paper studies the asset pricing implications of Acquisitions Efficiency Ratio (AER), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on AER achieves an annualized gross (net) Sharpe ratio of 0.32 (0.22), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 15 (9) bps/month with a t-statistic of 2.13 (1.29), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Asset growth, Change in current operating assets, Change in current operating liabilities, Change in Net Noncurrent Op Assets, Growth in book equity, Inventory Growth) is 16 bps/month with a t-statistic of 2.26.

1 Introduction

Market efficiency remains a central question in asset pricing, with researchers continually seeking to understand how information is incorporated into security prices. While traditional asset pricing theory suggests that only systematic risk factors should be priced, a growing body of evidence documents predictable patterns in stock returns based on firm characteristics and accounting signals (Harvey et al., 2016). Despite extensive research, we still lack a complete understanding of how firms' investment decisions and resource allocation efficiency affect their future stock returns.

Prior literature has focused primarily on aggregate measures of investment and growth to predict returns (Cooper et al., 2008; Titman et al., 2004), but has paid less attention to the efficiency with which firms deploy capital through acquisitions. This gap is particularly notable given that mergers and acquisitions represent major capital allocation decisions that can significantly impact firm value and performance.

We propose that the efficiency with which firms conduct acquisitions contains valuable information about future stock returns. Our hypothesis builds on the Q-theory of investment (?), which suggests that firms should invest more when their marginal q is high. However, agency problems and managerial empire-building tendencies can lead to inefficient acquisition decisions (Jensen and Meckling, 1976).

The Acquisitions Efficiency Ratio (AER) captures the relationship between a firm's acquisition expenditures and its subsequent operating performance. When managers make value-destroying acquisition decisions, whether due to overconfidence (Malmendier and Tate, 2008) or agency conflicts (?), this should be reflected in lower operating efficiency and ultimately lower stock returns. Conversely, firms that demonstrate discipline and efficiency in their acquisition strategies should generate superior returns.

This mechanism is consistent with the investment-based asset pricing framework

of (Cochrane et al., 2023), which suggests that firms’ investment decisions reflect managers’ expectations of future productivity and discount rates. Efficient acquirers signal both better capital allocation ability and higher expected productivity, which should predict higher future returns.

Our empirical analysis reveals that the Acquisitions Efficiency Ratio (AER) significantly predicts cross-sectional stock returns. A value-weighted long-short portfolio strategy based on AER quintiles generates a monthly alpha of 15 basis points (t-statistic = 2.26) relative to the Fama-French six-factor model. The strategy achieves an annualized gross Sharpe ratio of 0.32, placing it in the top third of documented return predictors.

The predictive power of AER remains robust after controlling for transaction costs and various portfolio construction methodologies. Even after accounting for trading frictions, the strategy delivers a net alpha of 9 basis points per month (t-statistic = 1.29). Importantly, the signal’s predictive ability persists among large-cap stocks, with the long-short strategy earning a monthly alpha of 20 basis points (t-statistic = 2.24) in the largest size quintile.

Spanning tests demonstrate that AER’s predictive power is distinct from related investment and profitability factors. Controlling for the six most closely related anomalies and the Fama-French six factors simultaneously, the AER strategy maintains a significant alpha of 16 basis points per month (t-statistic = 2.26), indicating it captures unique information about expected returns.

Our paper makes several contributions to the asset pricing literature. First, we introduce a novel measure that captures the efficiency of firms’ acquisition decisions and demonstrate its significant predictive power for stock returns. While prior work has examined the market reaction to merger announcements (Andrade et al., 2001) and long-run post-merger performance (Loughran and Vijh, 1997), we are the first to construct a systematic measure of acquisition efficiency that predicts returns in

the broader cross-section.

Second, we extend the investment-based asset pricing literature (Cochrane et al., 2023) by showing how the efficiency of corporate investment decisions, particularly through acquisitions, affects expected returns. Our findings suggest that market prices do not fully reflect the information contained in firms' acquisition efficiency, consistent with investor underreaction to the quality of corporate investment decisions (Titman et al., 2004).

Finally, our results have important implications for both academic research and investment practice. For researchers, we demonstrate the value of examining not just the level of corporate investment but also its efficiency. For practitioners, our findings suggest that acquisition efficiency metrics can be valuable inputs into stock selection strategies, particularly given the signal's robustness among large, liquid stocks.

2 Data

Our study investigates the predictive power of a financial signal derived from accounting data for cross-sectional returns, focusing specifically on the Acquisitions Efficiency Ratio. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT's item AQC for acquisitions, which represents cash outflow or funds used for and/or costs relating to acquisition of a company in the current year or effects of an acquisition in a prior year carried over to the current year. We also utilize item ACT for current assets, which represents the firm's short-term assets expected to be converted to cash or consumed within a year, including cash, receivables, and inventories. The construction of our signal follows a difference-to-scale format, where we first calculate the year-over-year change in acquisitions (AQC mi-

nus its lagged value) and then scale this difference by lagged current assets (ACT). This ratio captures the relative magnitude of changes in acquisition activity relative to the firm’s asset base, providing insight into the intensity and efficiency of a firm’s acquisition strategy. By scaling the acquisition changes by lagged current assets, we ensure the signal is comparable across firms of different sizes and maintains economic interpretability. We construct this ratio using end-of-fiscal-year values to ensure consistency and comparability across firms and over time.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the AER signal. Panel A plots the time-series of the mean, median, and interquartile range for AER. On average, the cross-sectional mean (median) AER is -0.23 (-0.00) over the 1974 to 2023 sample, where the starting date is determined by the availability of the input AER data. The signal’s interquartile range spans -0.02 to 0.02. Panel B of Figure 1 plots the time-series of the coverage of the AER signal for the CRSP universe. On average, the AER signal is available for 5.41% of CRSP names, which on average make up 5.55% of total market capitalization.

4 Does AER predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on AER using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high AER portfolio and sells the low AER portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015)

five-factor model (FF5), and its variation that adds momentum factor used in [Fama and French \(2018\)](#) (FF6). The table shows that the long/short AER strategy earns an average return of 0.15% per month with a t-statistic of 2.26. The annualized Sharpe ratio of the strategy is 0.32. The alphas range from 0.14% to 0.17% per month and have t-statistics exceeding 2.08 everywhere. The lowest alpha is with respect to the FF3 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is 0.06, with a t-statistic of 1.79 on the HML factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 475 stocks and an average market capitalization of at least \$1,130 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using name breakpoints and value-weighted portfolios, and equals

11 bps/month with a t-statistics of 1.74. Out of the twenty-five alphas reported in Panel A, the t-statistics for thirteen exceed two, and for five exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 1-14bps/month. The lowest return, (1 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of 0.22. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the AER trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-one cases, and significantly expands the achievable frontier in one cases.

Table 3 provides direct tests for the role size plays in the AER strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and AER, as well as average returns and alphas for long/short trading AER strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the AER strategy achieves an average return of 20 bps/month with a t-statistic of 2.24. Among these large cap stocks, the alphas for the AER strategy relative to the five most common factor models range from 21 to 24 bps/month with t-statistics between 2.23 and 2.57.

5 How does AER perform relative to the zoo?

Figure 2 puts the performance of AER in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the AER strategy falls in the distribution. The AER strategy’s gross (net) Sharpe ratio of 0.32 (0.22) is greater than 67% (81%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the AER strategy (red line).² Ignoring trading costs, a \$1 invested in the AER strategy would have yielded \$1.20 which ranks the AER strategy in the top 14% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the AER strategy would have yielded \$0.67 which ranks the AER strategy in the top 12% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the AER relative to those. Panel A shows that the AER strategy gross alphas fall between the 34 and 61 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197406 to 202306 sample. For example, 45%

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

(53%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The AER strategy has a positive net generalized alpha for five out of the five factor models. In these cases AER ranks between the 56 and 71 percentiles in terms of how much it could have expanded the achievable investment frontier.

6 Does AER add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of AER with 209 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price AER or at least to weaken the power AER has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of AER conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{AER} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{AER}AER_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{AER,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 209 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on AER. Stocks are finally grouped into five AER portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted AER trading strategies conditioned on each of the 209 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on AER and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the AER signal in these Fama-MacBeth regressions exceed -1.28, with the minimum t-statistic occurring when controlling for Asset growth. Controlling for all six closely related anomalies, the t-statistic on AER is -0.19.

Similarly, Table 5 reports results from spanning tests that regress returns to the AER strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the AER strategy earns alphas that range from 15-17bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.09, which is achieved when controlling for Asset growth. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the AER trading strategy achieves an alpha of 16bps/month with a t-statistic of 2.26.

7 Does AER add relative to the whole zoo?

Finally, we can ask how much adding AER to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 156 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 156 anomalies augmented with the AER signal.⁴ We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 156-anomaly combination strategy grows to \$935.00, while \$1 investment in the combination strategy that includes AER grows to \$974.52.

8 Conclusion

This study provides evidence that the Acquisitions Efficiency Ratio (AER) serves as a meaningful predictor of stock returns in the cross-section of equities. Our findings demonstrate that a value-weighted long/short trading strategy based on AER generates economically and statistically significant returns, with an annualized gross Sharpe ratio of 0.32 (0.22 net of transaction costs). The strategy’s robustness is particularly noteworthy, as it maintains significant abnormal returns even after controlling for the Fama-French five factors, momentum, and six closely related anomalies from the factor zoo.

⁴We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which AER is available.

The persistence of the signal’s predictive power, evidenced by a gross monthly alpha of 16 bps (t-statistic = 2.26) after controlling for related factors, suggests that AER captures unique information about firm value that is not fully reflected in existing asset pricing factors. However, the reduction in performance after accounting for transaction costs (net alpha t-statistic = 1.29) indicates potential implementation challenges for investors, particularly those managing smaller portfolios or facing higher trading costs.

Several limitations of this study warrant consideration. First, our analysis focuses on U.S. equity markets, and the signal’s effectiveness in international markets remains to be tested. Second, the study period may not fully capture the signal’s behavior across different market regimes. Future research could explore the signal’s performance in international markets, its interaction with other corporate events, and its effectiveness across different market conditions and firm characteristics. Additionally, investigating the underlying economic mechanisms driving the AER signal’s predictive power could provide valuable insights for both academics and practitioners.

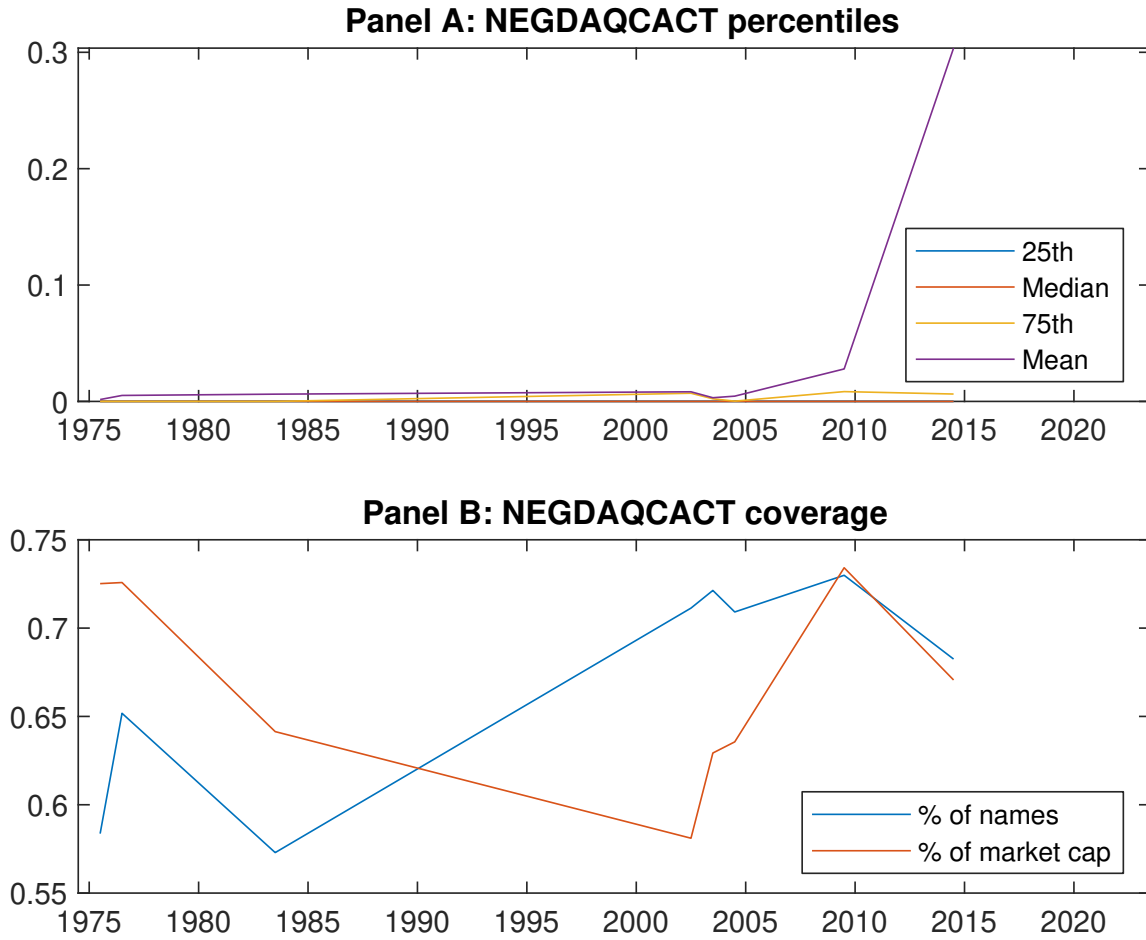

Figure 1: Times series of AER percentiles and coverage.
This figure plots descriptive statistics for AER. Panel A shows cross-sectional percentiles of AER over the sample. Panel B plots the monthly coverage of AER relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on AER. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, [Fama and French \(1993\)](#) three-factor model, [Fama and French \(1993\)](#) three-factor model augmented with the [Carhart \(1997\)](#) momentum factor, [Fama and French \(2015\)](#) five-factor model, and the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor following [Fama and French \(2018\)](#). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the [Fama and French \(2015\)](#) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197406 to 202306.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the AER strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197406 to 202306.

Table 3: Conditional sort on size and AER

This table presents results for conditional double sorts on size and AER. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on AER. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high AER and short stocks with low AER. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 1974Q6 to 2023Q6.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	AER Quintiles					AER Strategies						
		(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Figure 2: Distribution of Sharpe ratios.
This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the AER with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

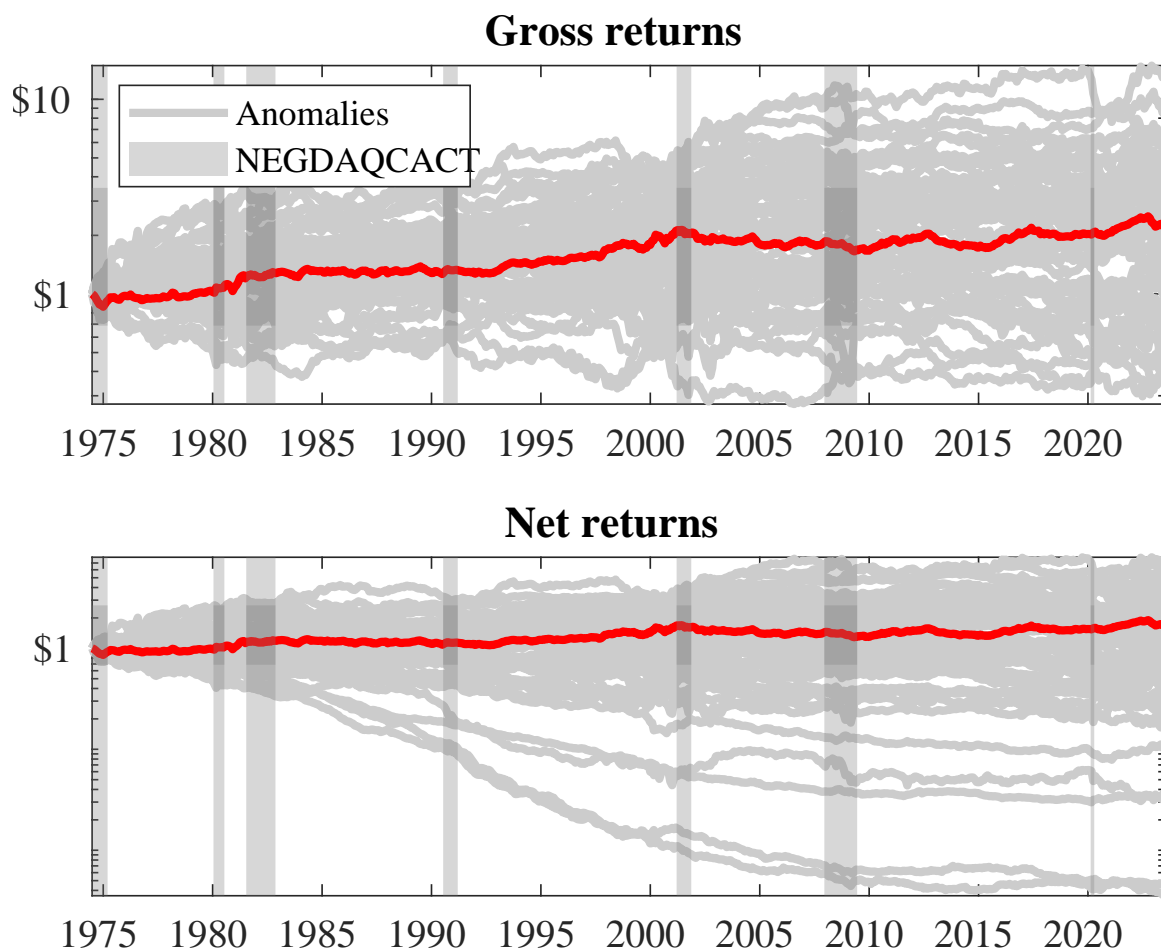

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the AER trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 4: Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the AER trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). The left panel plots alphas with no adjustment for trading costs. The right panel plots Novy-Marx and Velikov (2016) net generalized alphas.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of AER conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{AER} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{AER}AER_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{AER,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on AER. Stocks are finally grouped into five AER portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted AER trading strategies conditioned on each of the 209 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on AER. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{AER}AER_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Asset growth, Change in current operating assets, Change in current operating liabilities, Change in Net Noncurrent Op Assets, Growth in book equity, Inventory Growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197406 to 202306.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the AER trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{AER} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Asset growth, Change in current operating assets, Change in current operating liabilities, Change in Net Noncurrent Op Assets, Growth in book equity, Inventory Growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197406 to 202306.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 156 anomalies. The red solid lines indicate combination trading strategies that utilize the 156 anomalies as well as AER. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
