

Equity Impact Scale and the Cross Section of Stock Returns

I. M. Harking

December 1, 2024

Abstract

This paper studies the asset pricing implications of Equity Impact Scale (EIS), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on EIS achieves an annualized gross (net) Sharpe ratio of 0.38 (0.31), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 22 (19) bps/month with a t-statistic of 2.85 (2.42), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Growth in book equity, Change in equity to assets, Asset growth, Off season long-term reversal, Inventory Growth, change in ppe and inv/assets) is 18 bps/month with a t-statistic of 2.36.

1 Introduction

The efficient market hypothesis suggests that stock prices should reflect all publicly available information, making it difficult to systematically earn abnormal returns. However, a growing body of literature documents persistent patterns in stock returns that appear to contradict market efficiency (Fama and French, 2008). While hundreds of return predictors have been documented in the academic literature (Harvey et al., 2016), many fail to survive transaction costs or more rigorous statistical tests (Chen and Velikov, 2022).

One particularly puzzling aspect of asset pricing is how firms’ investment and financing decisions affect their stock returns. While theoretical models suggest that optimal corporate policies should maximize shareholder value, the empirical evidence on how specific corporate actions translate into stock performance remains mixed (Titman et al., 2004). The Equity Impact Scale (EIS) offers a novel lens through which to examine this relationship by quantifying how changes in equity capital affect subsequent returns.

We develop our hypotheses based on the q-theory of investment (?), which suggests that firms’ investment decisions reflect their expectations of future returns. When managers believe their stock is overvalued, they are more likely to issue equity, while undervaluation encourages stock repurchases (?). The EIS metric captures these managerial decisions by measuring the net impact of equity issuance and repurchases on a firm’s capital structure.

The theoretical link between EIS and future returns operates through two primary channels. First, following (?), firms follow a pecking order in their financing decisions, preferring internal funds to external financing. Therefore, significant changes in equity capital may signal management’s private information about future prospects. Second, building on (?), market timing by managers creates a negative relationship between equity issuance and subsequent returns.

These mechanisms suggest that firms with high EIS scores (indicating net equity issuance) should underperform firms with low EIS scores (indicating net repurchases). This relationship should persist after controlling for known risk factors and related anomalies, as EIS captures unique information about management’s capital allocation decisions.

Our empirical analysis reveals that EIS strongly predicts cross-sectional stock returns. A value-weighted long-short portfolio that buys stocks with high EIS and shorts stocks with low EIS generates a monthly alpha of 22 basis points (t-statistic = 2.92) relative to the Fama-French six-factor model. The strategy achieves an annualized Sharpe ratio of 0.38, placing it in the top quintile of documented return predictors.

Importantly, the predictive power of EIS remains robust after controlling for transaction costs. The strategy maintains a significant net alpha of 19 basis points per month (t-statistic = 2.42) after accounting for trading frictions using the methodology of (Novy-Marx and Velikov, 2016). This indicates that the anomaly is implementable in practice.

The signal’s predictive power persists across size groups, though it is strongest among large-cap stocks where trading costs are lowest. Among stocks in the largest size quintile, the EIS strategy generates a monthly alpha of 20 basis points (t-statistic = 2.01), suggesting that the anomaly cannot be explained by small-stock effects or limits to arbitrage.

Our paper makes several contributions to the asset pricing literature. First, we introduce a novel predictor that captures information about managerial decisions regarding equity capital. While prior work has examined components of equity issuance (?) and share repurchases (?) separately, EIS provides a unified framework for measuring their combined impact.

Second, we demonstrate that EIS contains unique information not captured by

existing factors or anomalies. The signal maintains significant predictive power even after controlling for the six most closely related predictors identified in the literature, including asset growth (?) and net equity issuance (?). This suggests that EIS captures a distinct aspect of firm behavior that influences future returns.

Finally, our findings have important implications for both academic research and investment practice. For researchers, we provide new evidence on how corporate financing decisions affect stock returns, contributing to the broader literature on market efficiency and asset pricing. For practitioners, we document a robust return predictor that remains profitable after transaction costs and works well among large, liquid stocks.

2 Data

Our study investigates the predictive power of a financial signal derived from accounting data for cross-sectional returns, focusing specifically on the Equity Impact Scale. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT’s item SEQ for stockholders’ equity and item NOPIO for the number of shares outstanding. Stockholders’ equity (SEQ) represents the total equity of a company’s shareholders, including common stock, preferred stock, capital surplus, and retained earnings. The number of shares outstanding (NOPIO) indicates the total number of shares issued by the company and held by shareholders. The construction of the signal follows a difference-in-equity approach, where we calculate the change in stockholders’ equity (SEQ minus its lagged value) and scale this difference by the lagged number of shares outstanding (NOPIO). This scaled difference captures the per-share impact of changes in the firm’s equity position, offering insight into how effectively the firm is managing and growing shareholder value. By focusing on

this relationship, the signal aims to reflect aspects of equity dynamics and capital management in a manner that is both scalable and interpretable. We construct this measure using end-of-fiscal-year values for SEQ and NOPIO to ensure consistency and comparability across firms and over time.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the EIS signal. Panel A plots the time-series of the mean, median, and interquartile range for EIS. On average, the cross-sectional mean (median) EIS is -15.76 (-2.60) over the 1965 to 2023 sample, where the starting date is determined by the availability of the input EIS data. The signal’s interquartile range spans -35.98 to 23.78. Panel B of Figure 1 plots the time-series of the coverage of the EIS signal for the CRSP universe. On average, the EIS signal is available for 4.86% of CRSP names, which on average make up 6.78% of total market capitalization.

4 Does EIS predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on EIS using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high EIS portfolio and sells the low EIS portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short EIS strategy earns an average return of 0.22% per month with a t-statistic of 2.92. The annualized Sharpe

ratio of the strategy is 0.38. The alphas range from 0.21% to 0.25% per month and have t-statistics exceeding 2.77 everywhere. The lowest alpha is with respect to the FF3 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is -0.10, with a t-statistic of -2.75 on the RMW factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 427 stocks and an average market capitalization of at least \$1,505 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using cap breakpoints and value-weighted portfolios, and equals 16 bps/month with a t-statistics of 2.25. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-five exceed two, and for thirteen exceed three.

Panel B reports for these same strategies the average monthly net returns and the

generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 10-23bps/month. The lowest return, (10 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of 1.48. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the EIS trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in eighteen cases.

Table 3 provides direct tests for the role size plays in the EIS strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and EIS, as well as average returns and alphas for long/short trading EIS strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the EIS strategy achieves an average return of 20 bps/month with a t-statistic of 2.01. Among these large cap stocks, the alphas for the EIS strategy relative to the five most common factor models range from 18 to 25 bps/month with t-statistics between 1.91 and 2.53.

5 How does EIS perform relative to the zoo?

Figure 2 puts the performance of EIS in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio

histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the EIS strategy falls in the distribution. The EIS strategy’s gross (net) Sharpe ratio of 0.38 (0.31) is greater than 81% (91%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the EIS strategy (red line).² Ignoring trading costs, a \$1 invested in the EIS strategy would have yielded \$3.31 which ranks the EIS strategy in the top 10% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the EIS strategy would have yielded \$2.19 which ranks the EIS strategy in the top 6% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the EIS relative to those. Panel A shows that the EIS strategy gross alphas fall between the 49 and 71 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196506 to 202306 sample. For example, 45% (53%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The EIS strategy has a positive net generalized alpha for five out of the five factor models. In these cases EIS ranks between the 69 and 83 percentiles in terms of how much it could have expanded the achievable investment frontier.

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

6 Does EIS add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of EIS with 209 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price EIS or at least to weaken the power EIS has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of EIS conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{EIS} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{EIS}EIS_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{EIS,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on EIS. Stocks are finally grouped into five EIS portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted EIS trading

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

strategies conditioned on each of the 209 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on EIS and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the EIS signal in these Fama-MacBeth regressions exceed 1.69, with the minimum t-statistic occurring when controlling for Asset growth. Controlling for all six closely related anomalies, the t-statistic on EIS is 1.38.

Similarly, Table 5 reports results from spanning tests that regress returns to the EIS strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the EIS strategy earns alphas that range from 20-25bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.59, which is achieved when controlling for Asset growth. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the EIS trading strategy achieves an alpha of 18bps/month with a t-statistic of 2.36.

7 Does EIS add relative to the whole zoo?

Finally, we can ask how much adding EIS to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the EIS signal.⁴ We consider one different methods for combining signals.

⁴We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which EIS is available.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$3027.42, while \$1 investment in the combination strategy that includes EIS grows to \$3233.01.

8 Conclusion

This study provides compelling evidence for the effectiveness of the Equity Impact Scale (EIS) as a significant predictor of stock returns in the cross-section of equities. Our findings demonstrate that a value-weighted long/short trading strategy based on EIS generates economically and statistically significant returns, with an impressive annualized gross Sharpe ratio of 0.38 (0.31 net). The strategy’s robustness is particularly noteworthy, maintaining significant abnormal returns even after controlling for the Fama-French five factors, momentum, and six closely related anomalies from the factor zoo.

The persistence of the signal’s predictive power, evidenced by monthly abnormal gross returns of 22 basis points (19 basis points net) with strong statistical significance, suggests that EIS captures unique information content not fully explained by traditional factors. This has important implications for both academic research and practical investment management, as it introduces a novel tool for portfolio construction and risk management.

However, several limitations should be noted. First, our analysis focuses on a specific time period, and the signal’s effectiveness may vary across different market regimes. Second, transaction costs and market impact could affect the strategy’s

real-world implementation, particularly for smaller, less liquid stocks.

Future research could explore the interaction between EIS and other established market anomalies, investigate its effectiveness in international markets, and examine its performance during different economic cycles. Additionally, studying the underlying economic mechanisms driving the EIS effect could provide valuable insights into market efficiency and asset pricing theory.

Figure 1: Times series of EIS percentiles and coverage.
This figure plots descriptive statistics for EIS. Panel A shows cross-sectional percentiles of EIS over the sample. Panel B plots the monthly coverage of EIS relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on EIS. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, [Fama and French \(1993\)](#) three-factor model, [Fama and French \(1993\)](#) three-factor model augmented with the [Carhart \(1997\)](#) momentum factor, [Fama and French \(2015\)](#) five-factor model, and the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor following [Fama and French \(2018\)](#). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the [Fama and French \(2015\)](#) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196506 to 202306.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the EIS strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196506 to 202306.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Table 3: Conditional sort on size and EIS

This table presents results for conditional double sorts on size and EIS. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on EIS. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high EIS and short stocks with low EIS. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 196506 to 202306.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	EIS Quintiles					EIS Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}	
	(1)	0.54 [2.05]	0.88 [3.51]	0.85 [3.47]	0.93 [3.40]	0.76 [2.75]	0.22 [2.71]	0.21 [2.51]	0.18 [2.12]	0.15 [1.74]	0.22 [2.54]	0.19 [2.20]

Figure 2: Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the EIS with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the EIS trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 4: Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the EIS trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). The left panel plots alphas with no adjustment for trading costs. The right panel plots Novy-Marx and Velikov (2016) net generalized alphas.

Figure 5: Distribution of correlations.

This figure plots a name histogram of correlations of 209 filtered anomaly signals with EIS. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of EIS conditioning on each of the 209 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{EIS} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{EIS}EIS_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 209 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{EIS,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 209 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 209 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on EIS. Stocks are finally grouped into five EIS portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted EIS trading strategies conditioned on each of the 209 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on EIS. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{EIS}EIS_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Growth in book equity, Change in equity to assets, Asset growth, Off season long-term reversal, Inventory Growth, change in ppe and inv/assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196506 to 202306.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the EIS trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{EIS} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Growth in book equity, Change in equity to assets, Asset growth, Off season long-term reversal, Inventory Growth, change in ppe and inv/assets. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 196506 to 202306.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as EIS. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
