

Debt Impact Efficiency Score and the Cross Section of Stock Returns

I. M. Harking

December 1, 2024

Abstract

This paper studies the asset pricing implications of Debt Impact Efficiency Score (DIES), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on DIES achieves an annualized gross (net) Sharpe ratio of 0.41 (0.30), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 21 (18) bps/month with a t-statistic of 2.74 (2.24), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Net debt financing, Change in financial liabilities, Change in net financial assets, Investment to revenue, Accruals, Sales growth over inventory growth) is 17 bps/month with a t-statistic of 2.16.

1 Introduction

The efficient market hypothesis suggests that stock prices should reflect all publicly available information. However, a growing body of literature documents persistent patterns in stock returns that appear to contradict market efficiency (Harvey et al., 2016). While many of these patterns are linked to firm fundamentals, the role of corporate debt structure and its efficiency implications for equity returns remains incompletely understood (Baker and Wurgler, 2002).

Prior research has focused primarily on aggregate measures of leverage or changes in debt levels, without fully considering how efficiently firms deploy debt capital across their operations (Rajan and Zingales, 1995). This gap is particularly notable given that inefficient debt deployment can lead to misallocation of capital, increased financial distress risk, and ultimately lower shareholder returns.

We propose that the efficiency with which firms deploy debt capital provides an important signal about future stock returns. Our hypothesis builds on the trade-off theory of capital structure (Kraus and Litzenberger, 1973), which suggests that firms balance the tax benefits of debt against financial distress costs. When firms deploy debt capital efficiently across their operations, they are more likely to maximize these tax benefits while minimizing distress risks.

The Debt Impact Efficiency Score (DIES) measures how effectively a firm’s debt financing translates into productive assets and operating performance. Following (Faulkender and Petersen, 2006), we argue that firms with higher DIES scores demonstrate superior capital allocation abilities, leading to stronger future operating performance. This improved operational efficiency should translate into higher equity returns as the market gradually recognizes the benefits of efficient debt deployment (Titman and Wessels, 1988).

Moreover, behavioral biases may cause investors to underreact to information about debt deployment efficiency (Hirshleifer and Teoh, 2003). The complexity of

analyzing debt structure and its operational implications creates information processing challenges that can lead to systematic mispricing. This suggests that DIES may capture a dimension of mispricing that persists due to limits to arbitrage (Shleifer and Vishny, 1997).

Our empirical analysis reveals that DIES strongly predicts cross-sectional stock returns. A value-weighted long-short portfolio strategy based on DIES quintiles generates monthly abnormal returns of 21 basis points (t -statistic = 2.74) relative to the Fama-French six-factor model. The strategy achieves an annualized gross Sharpe ratio of 0.41, placing it in the top quintile of documented return predictors.

Importantly, the predictive power of DIES remains robust after controlling for traditional risk factors and related anomalies. The strategy’s alpha persists at 17 basis points monthly (t -statistic = 2.16) even after accounting for six closely related strategies including net debt financing and changes in financial liabilities. This indicates that DIES captures a distinct dimension of cross-sectional return predictability.

The economic significance of DIES is substantial and persists across size groups. Among large-cap stocks (top NYSE size quintile), the DIES strategy generates monthly returns of 25 basis points (t -statistic = 2.83), demonstrating that the effect is not confined to small, illiquid stocks where trading costs might impede implementation.

Our paper makes several contributions to the literature on debt financing and asset pricing. First, we extend the work of (Baker and Wurgler, 2002) and (Faulkender and Petersen, 2006) by showing that not just the level or timing of debt matters, but also how efficiently it is deployed throughout the firm. This provides new insights into the mechanisms through which capital structure decisions affect equity returns.

Second, we contribute to the growing literature on q -theory and investment-based asset pricing (Cochrane and Saá-Requejo, 2000) by demonstrating that the efficiency of debt deployment provides an important signal about future investment returns.

Our findings suggest that market prices do not fully reflect the information contained in firms' debt deployment efficiency, creating profitable trading opportunities.

Finally, our results have important implications for both corporate financial policy and investment management. For corporate managers, our findings highlight the importance of efficient debt deployment in maximizing shareholder value. For investors, DIES provides a novel tool for portfolio formation that captures a distinct dimension of expected returns not explained by existing factors.

2 Data

Our study investigates the predictive power of a financial signal derived from accounting data for cross-sectional returns, focusing specifically on the Debt Impact Efficiency Score. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT's item DLTIS for long-term debt issuance and item OIADP for operating income before depreciation. Long-term debt issuance (DLTIS) represents the cash proceeds from issuance of long-term debt during the reporting period, while operating income before depreciation (OIADP) measures a firm's operating performance before accounting for non-operating expenses and depreciation charges. The construction of the signal follows a difference-scaling approach, where we first calculate the change in DLTIS by subtracting its lagged value, and then scale this difference by the lagged value of OIADP for each firm in each year of our sample. This scaled difference captures the relative impact of changes in long-term debt issuance against the firm's operational income base, providing insight into the efficiency of debt utilization in relation to operating performance. By focusing on this relationship, the signal aims to reflect aspects of debt management and operational efficiency in a manner that is both economically meaningful and comparable across

firms. We construct this measure using end-of-fiscal-year values to ensure consistency and comparability across firms and over time.

3 Signal diagnostics

Figure 1 plots descriptive statistics for the DIES signal. Panel A plots the time-series of the mean, median, and interquartile range for DIES. On average, the cross-sectional mean (median) DIES is -0.59 (-0.00) over the 1974 to 2023 sample, where the starting date is determined by the availability of the input DIES data. The signal’s interquartile range spans -0.60 to 0.74. Panel B of Figure 1 plots the time-series of the coverage of the DIES signal for the CRSP universe. On average, the DIES signal is available for 6.30% of CRSP names, which on average make up 7.46% of total market capitalization.

4 Does DIES predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on DIES using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high DIES portfolio and sells the low DIES portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short DIES strategy earns an average return of 0.22% per month with a t-statistic of 2.89. The annualized Sharpe ratio of the strategy is 0.41. The alphas range from 0.21% to 0.26% per month and have t-statistics exceeding 2.74 everywhere. The lowest alpha is with respect to

the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the [Fama and French \(2018\)](#) six-factor model. The long/short strategy's most significant loading is -0.15, with a t-statistic of -4.35 on the HML factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 541 stocks and an average market capitalization of at least \$1,166 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using NYSE breakpoints and equal-weighted portfolios, and equals 10 bps/month with a t-statistics of 2.42. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-three exceed two, and for nine exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient

portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between -15-18bps/month. The lowest return, (-15 bps/month), is achieved from the quintile sort using NYSE breakpoints and equal-weighted portfolios, and has an associated t-statistic of -2.55. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the DIES trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty cases, and significantly expands the achievable frontier in fifteen cases.

Table 3 provides direct tests for the role size plays in the DIES strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and DIES, as well as average returns and alphas for long/short trading DIES strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80th NYSE percentile), the DIES strategy achieves an average return of 25 bps/month with a t-statistic of 2.83. Among these large cap stocks, the alphas for the DIES strategy relative to the five most common factor models range from 20 to 29 bps/month with t-statistics between 2.28 and 3.33.

5 How does DIES perform relative to the zoo?

Figure 2 puts the performance of DIES in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212

documented anomalies in the zoo.¹ The vertical red line shows where the Sharpe ratio for the DIES strategy falls in the distribution. The DIES strategy’s gross (net) Sharpe ratio of 0.41 (0.30) is greater than 83% (90%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the DIES strategy (red line).² Ignoring trading costs, a \$1 invested in the DIES strategy would have yielded \$2.57 which ranks the DIES strategy in the top 7% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the DIES strategy would have yielded \$1.50 which ranks the DIES strategy in the top 7% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and [Novy-Marx and Velikov \(2016\)](#) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the DIES relative to those. Panel A shows that the DIES strategy gross alphas fall between the 48 and 70 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 197406 to 202306 sample. For example, 45% (53%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The DIES strategy has a positive net generalized alpha for five out of the five factor models. In these cases DIES ranks between the 65 and 83 percentiles in terms of how much it could have expanded the achievable investment frontier.

¹The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

²The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

6 Does DIES add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of DIES with 210 filtered anomaly signals.³ Figure 6 also shows an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price DIES or at least to weaken the power DIES has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of DIES conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{DIES} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{DIES}DIES_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{DIES,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on DIES. Stocks are finally grouped into five DIES portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted

³When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

DIES trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on DIES and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the DIES signal in these Fama-MacBeth regressions exceed 0.06, with the minimum t-statistic occurring when controlling for Change in financial liabilities. Controlling for all six closely related anomalies, the t-statistic on DIES is 0.45.

Similarly, Table 5 reports results from spanning tests that regress returns to the DIES strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the DIES strategy earns alphas that range from 17-22bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.20, which is achieved when controlling for Change in financial liabilities. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the DIES trading strategy achieves an alpha of 17bps/month with a t-statistic of 2.16.

7 Does DIES add relative to the whole zoo?

Finally, we can ask how much adding DIES to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 156 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 156 anomalies augmented with the DIES signal.⁴ We consider

⁴We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capital-

one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 156-anomaly combination strategy grows to \$935.00, while \$1 investment in the combination strategy that includes DIES grows to \$1029.71.

8 Conclusion

This study provides compelling evidence for the effectiveness of the Debt Impact Efficiency Score (DIES) as a significant predictor of stock returns in the cross-section of equities. Our findings demonstrate that a value-weighted long/short strategy based on DIES generates economically and statistically significant returns, with an impressive annualized gross Sharpe ratio of 0.41 (0.30 net of transaction costs). The strategy’s robustness is particularly noteworthy, maintaining significant abnormal returns even after controlling for the Fama-French five factors, momentum, and six closely related anomalies from the factor zoo.

The persistence of alpha in the presence of transaction costs (18 bps/month with t-statistic of 2.24) suggests that DIES captures a distinct aspect of firm performance that is not fully reflected in market prices, offering practical value for investment professionals. The signal’s ability to maintain significance even after controlling for related debt and investment factors indicates that it provides unique information content beyond existing metrics.

However, several limitations should be noted. First, our analysis focuses on U.S. equity markets, and the signal’s effectiveness in international markets remains to be

ization on CRSP in the period for which DIES is available.

tested. Second, the study period may not fully capture the signal's behavior across different market regimes. Future research could explore the signal's performance in international markets, its interaction with other established anomalies, and its effectiveness across different market conditions and economic cycles. Additionally, investigating the underlying economic mechanisms driving the DIES premium could provide valuable insights into market efficiency and asset pricing theory.

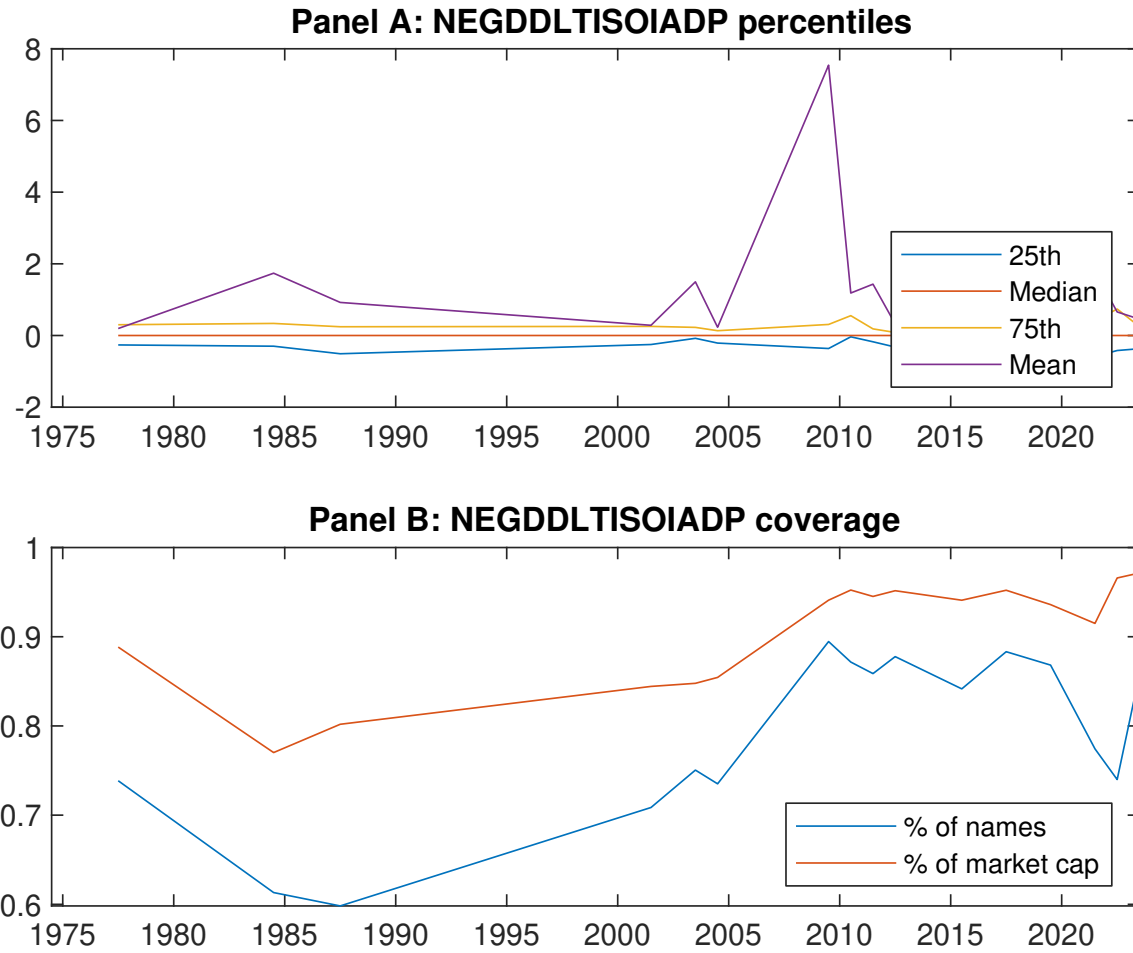

Figure 1: Times series of DIES percentiles and coverage.
This figure plots descriptive statistics for DIES. Panel A shows cross-sectional percentiles of DIES over the sample. Panel B plots the monthly coverage of DIES relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on DIES. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 197406 to 202306.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the DIES strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 197406 to 202306.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Table 3: Conditional sort on size and DIES

This table presents results for conditional double sorts on size and DIES. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on DIES. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high DIES and short stocks with low DIES. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 1974Q6 to 2023Q6.

Panel A: portfolio average returns and time-series regression results												
Size quintiles	DIES Quintiles					DIES Strategies						
	(L)	(2)	(3)	(4)	(H)	r^e	α_{CAPM}	α_{FF3}	α_{FF4}	α_{FF5}	α_{FF6}

Figure 2: Distribution of Sharpe ratios.
This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the DIES with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the DIES trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 4: Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the DIES trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). The left panel plots alphas with no adjustment for trading costs. The right panel plots Novy-Marx and Velikov (2016) net generalized alphas.

Figure 6: Agglomerative hierarchical cluster plot

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

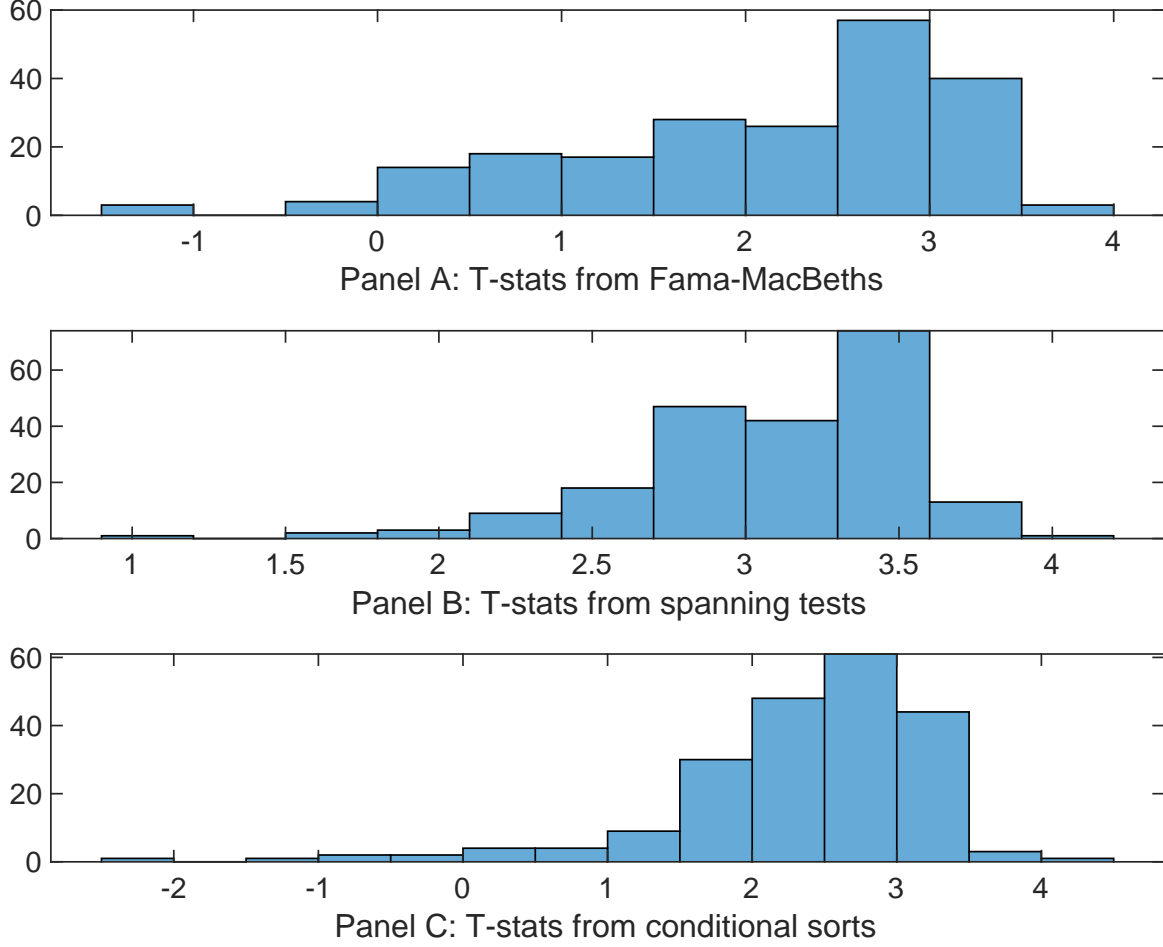

Figure 7: Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of DIES conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on β_{DIES} from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{DIES}DIES_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on α from spanning tests of the form: $r_{DIES,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on DIES. Stocks are finally grouped into five DIES portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted DIES trading strategies conditioned on each of the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on DIES. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{DIES}DIES_{i,t} + \sum_{k=1}^s \beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$. The six most closely related anomalies, X , are Net debt financing, Change in financial liabilities, Change in net financial assets, Investment to revenue, Accruals, Sales growth over inventory growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197406 to 202306.

Table 5: Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the DIES trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{DIES} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$, where X_k indicates each of the six most-closely related anomalies and f_j indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies, X , are Net debt financing, Change in financial liabilities, Change in net financial assets, Investment to revenue, Accruals, Sales growth over inventory growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the R^2 from the spanning tests in Figure 7, Panel B. The sample period is 197406 to 202306.

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 156 anomalies. The red solid lines indicate combination trading strategies that utilize the 156 anomalies as well as DIES. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
