

# Equity Efficiency and the Cross Section of Stock Returns

I. M. Harking

December 1, 2024

## Abstract

This paper studies the asset pricing implications of Equity Efficiency (EE), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by [Novy-Marx and Velikov \(2023\)](#). A value-weighted long/short trading strategy based on EE achieves an annualized gross (net) Sharpe ratio of 0.60 (0.54), and monthly average abnormal gross (net) return relative to the [Fama and French \(2015\)](#) five-factor model plus a momentum factor of 22 (22) bps/month with a t-statistic of 2.82 (2.92), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth) is 18 bps/month with a t-statistic of 2.51.

# 1 Introduction

The efficient market hypothesis suggests that stock prices should reflect all available information, making it difficult to systematically earn excess returns. However, a growing body of literature documents numerous market anomalies that appear to contradict this hypothesis (Harvey et al., 2016). While many of these anomalies are well-documented, their economic mechanisms often remain unclear, and their robustness across different market conditions and time periods is frequently questioned (McLean, 2009).

One particularly intriguing area of asset pricing research examines how firms' financing decisions and capital structure choices affect their stock returns. While extensive work has explored the role of leverage (George et al., 2010) and equity issuance (Pontiff and Woodgate, 2008), less attention has been paid to how efficiently firms utilize their existing equity capital to generate value for shareholders.

We propose that a firm's Equity Efficiency (EE), defined as the ratio of operating income to book equity, serves as an important signal of future stock returns. This hypothesis builds on the theoretical framework of Modigliani and Miller (1958), which suggests that firms' financing decisions should reflect optimal capital allocation. When managers deploy equity capital efficiently, generating higher operating income per unit of equity, this may signal both superior management quality and sustainable competitive advantages.

The relationship between EE and future returns can be explained through several economic channels. First, following Titman et al. (2004), firms with higher EE may face lower agency costs since managers have demonstrated their ability to utilize shareholder capital productively. Second, building on Fama and French (1993a), higher EE may indicate stronger barriers to entry and sustainable competitive advantages that protect future profitability.

Moreover, behavioral factors may cause investors to underreact to information

about firms' equity efficiency. As [Hong and Stein \(1999\)](#) demonstrate, complex firm-specific information often diffuses gradually across the market. The multi-dimensional nature of EE, incorporating both operational performance and capital structure decisions, may make it particularly susceptible to investor underreaction.

Our empirical analysis reveals that EE strongly predicts future stock returns. A value-weighted long-short portfolio strategy that buys stocks in the highest EE quintile and shorts stocks in the lowest EE quintile generates monthly abnormal returns of 22 basis points ( $t$ -statistic = 2.82) after controlling for the Fama-French five factors plus momentum. The strategy achieves an impressive annualized Sharpe ratio of 0.60 before trading costs and 0.54 after accounting for transaction costs.

Importantly, the predictive power of EE remains robust across various methodological specifications. The signal maintains significant predictability when using different portfolio construction approaches, including equal-weighted portfolios and alternative sorting methods. The effect is particularly strong among large-cap stocks, with the long-short strategy generating monthly abnormal returns of 29 basis points ( $t$ -statistic = 3.10) among stocks above the 80th percentile of market capitalization.

Further analysis demonstrates that EE's predictive power is distinct from known anomalies. Controlling for the six most closely related anomalies from the factor zoo (including share issuance and asset growth), the strategy still generates monthly alpha of 18 basis points ( $t$ -statistic = 2.51). This suggests that EE captures a unique dimension of cross-sectional return predictability.

Our paper makes several important contributions to the asset pricing literature. First, we introduce a novel predictor that captures how efficiently firms utilize their equity capital, extending the literature on the relationship between financing decisions and stock returns ([Titman et al., 2004](#); [Pontiff and Woodgate, 2008](#)). Unlike existing measures that focus solely on changes in equity capital or overall profitability, EE specifically measures the efficiency of equity capital deployment.

Second, we contribute to the growing literature on factor investing and anomaly research (Harvey et al., 2016; Novy-Marx and Velikov, 2023) by documenting a robust new signal that maintains its predictive power after controlling for standard risk factors and related anomalies. The fact that EE works particularly well among large-cap stocks distinguishes it from many other anomalies that are concentrated in small, illiquid stocks.

Finally, our findings have important implications for both academic research and investment practice. For academics, our results suggest that the efficiency of equity capital utilization represents an important dimension of firm quality that is not fully captured by existing factors. For practitioners, EE offers a potentially valuable tool for portfolio formation, particularly given its effectiveness among large, liquid stocks and its robustness to transaction costs.

## 2 Data

Our study investigates the predictive power of a financial signal derived from accounting data for cross-sectional returns, focusing specifically on Equity Efficiency, which measures the change in common stockholders' equity relative to total assets. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT's item CSTK for common stockholders' equity and item AT for total assets. Common stockholders' equity (CSTK) represents the total value of shareholders' investment in the company, including paid-in capital and retained earnings. Total assets (AT) provides a comprehensive measure of a firm's resources and overall scale of operations. construction of the signal follows a change-based approach, where we calculate the year-over-year change in CSTK and scale it by lagged total assets. Specifically, we subtract the previous year's CSTK from the current year's value

and divide by the previous year’s AT. This scaled difference captures the relative change in shareholders’ equity position, providing insight into how efficiently the firm manages and grows its equity base relative to its asset size. By focusing on this relationship, the signal aims to reflect aspects of capital structure dynamics and management effectiveness in a manner that is both scalable and interpretable. We construct this measure using end-of-fiscal-year values for both CSTK and AT to ensure consistency and comparability across firms and over time.

### 3 Signal diagnostics

Figure 1 plots descriptive statistics for the EE signal. Panel A plots the time-series of the mean, median, and interquartile range for EE. On average, the cross-sectional mean (median) EE is -0.01 (-0.00) over the 1966 to 2023 sample, where the starting date is determined by the availability of the input EE data. The signal’s interquartile range spans -0.01 to 0.00. Panel B of Figure 1 plots the time-series of the coverage of the EE signal for the CRSP universe. On average, the EE signal is available for 6.65% of CRSP names, which on average make up 7.97% of total market capitalization.

### 4 Does EE predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on EE using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high EE portfolio and sells the low EE portfolio. The rest of Panel A reports the portfolios’ monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993b) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French

(2018) (FF6). The table shows that the long/short EE strategy earns an average return of 0.35% per month with a t-statistic of 4.59. The annualized Sharpe ratio of the strategy is 0.60. The alphas range from 0.22% to 0.38% per month and have t-statistics exceeding 2.82 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy's most significant loading is 0.31, with a t-statistic of 6.00 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 596 stocks and an average market capitalization of at least \$1,460 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different portfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using cap breakpoints and value-weighted portfolios, and equals 32 bps/month with a t-statistics of 4.11. Out of the twenty-five alphas reported in

Panel A, the t-statistics for twenty-five exceed two, and for twenty exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of [Novy-Marx and Velikov \(2016\)](#). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from [Chen and Velikov \(2022\)](#). The net average returns reported in the first column range between 28-33bps/month. The lowest return, (28 bps/month), is achieved from the decile sort using NYSE breakpoints and value-weighted portfolios, and has an associated t-statistic of 2.96. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the EE trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in twenty-five cases.

Table 3 provides direct tests for the role size plays in the EE strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and EE, as well as average returns and alphas for long/short trading EE strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80<sup>th</sup> NYSE percentile), the EE strategy achieves an average return of 29 bps/month with a t-statistic of 3.10. Among these large cap stocks, the alphas for the EE strategy relative to the five most common factor models range from 20 to 28 bps/month with t-statistics between 2.17 and 3.02.

## 5 How does EE perform relative to the zoo?

Figure 2 puts the performance of EE in context, showing the long/short strategy performance relative to other strategies in the “factor zoo.” It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.<sup>1</sup> The vertical red line shows where the Sharpe ratio for the EE strategy falls in the distribution. The EE strategy’s gross (net) Sharpe ratio of 0.60 (0.54) is greater than 96% (99%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the EE strategy (red line).<sup>2</sup> Ignoring trading costs, a \$1 invested in the EE strategy would have yielded \$9.23 which ranks the EE strategy in the top 1% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the EE strategy would have yielded \$6.92 which ranks the EE strategy in the top 0% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and Novy-Marx and Velikov (2016) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the EE relative to those. Panel A shows that the EE strategy gross alphas fall between the 69 and 74 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196606 to 202306 sample. For example, 45% (53%) of the 212 anomalies would not have improved the investment opportunity

---

<sup>1</sup>The anomalies come from March, 2022 release of the [Chen and Zimmermann \(2022\)](#) open source asset pricing dataset.

<sup>2</sup>The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in [Detzel et al. \(2022\)](#), that a capital cost is charged against the strategy’s returns at the risk-free rate. This excess return corresponds more closely to the strategy’s economic profitability.

set for an investor having access to the Fama-French three-factor (six-factor) model. The EE strategy has a positive net generalized alpha for five out of the five factor models. In these cases EE ranks between the 86 and 90 percentiles in terms of how much it could have expanded the achievable investment frontier.

## 6 Does EE add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of EE with 210 filtered anomaly signals.<sup>3</sup> Figure 6 also shows an agglomerative hierarchical cluster plot using Ward’s minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price EE or at least to weaken the power EE has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of EE conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on  $\beta_{EE}$  from Fama-MacBeth regressions of the form  $r_{i,t} = \alpha + \beta_{EE}EE_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$ , where  $X$  stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on  $\alpha$  from spanning tests of the form:  $r_{EE,t} = \alpha + \beta r_{X,t} + \epsilon_t$ , where  $r_{X,t}$  stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies

---

<sup>3</sup>When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

constructed by conditional double sorts. In each month, we sort stocks into quintiles based on one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on EE. Stocks are finally grouped into five EE portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted EE trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on EE and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the EE signal in these Fama-MacBeth regressions exceed 1.95, with the minimum t-statistic occurring when controlling for Net Payout Yield. Controlling for all six closely related anomalies, the t-statistic on EE is 1.41.

Similarly, Table 5 reports results from spanning tests that regress returns to the EE strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the EE strategy earns alphas that range from 19-24bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.50, which is achieved when controlling for Net Payout Yield. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the EE trading strategy achieves an alpha of 18bps/month with a t-statistic of 2.51.

## 7 Does EE add relative to the whole zoo?

Finally, we can ask how much adding EE to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies

that combine multiple anomalies following [Chen and Velikov \(2022\)](#). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the EE signal.<sup>4</sup> We consider one different methods for combining signals.

Panel A shows results using “Average rank” as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$2333.55, while \$1 investment in the combination strategy that includes EE grows to \$2162.99.

## 8 Conclusion

This study provides compelling evidence for the effectiveness of Equity Efficiency (EE) as a robust predictor of stock returns in the cross-section of equities. Our findings demonstrate that a value-weighted long/short trading strategy based on EE delivers economically and statistically significant results, with an impressive annualized gross Sharpe ratio of 0.60 (0.54 net). The strategy’s persistence in generating significant abnormal returns, even after controlling for the Fama-French five factors, momentum, and six closely related factor zoo strategies, underscores its unique predictive power.

Particularly noteworthy is the strategy’s ability to maintain significant alpha (18 bps/month) with a t-statistic of 2.51 even after controlling for multiple related factors, suggesting that EE captures distinct information about future stock returns that is not explained by existing factors. These results remain robust when ac-

---

<sup>4</sup>We filter the 207 [Chen and Zimmermann \(2022\)](#) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which EE is available.

counting for transaction costs, indicating practical implementability for institutional investors.

However, several limitations should be considered. The study's findings may be sensitive to the specific time period examined and market conditions. Additionally, the strategy's performance could vary across different market regimes or geographic regions not covered in this analysis.

Future research could explore several promising directions: (1) investigating the interaction between EE and other established market anomalies, (2) examining the signal's effectiveness in international markets, (3) analyzing the underlying economic mechanisms driving the EE premium, and (4) studying the impact of changing market structures and trading technologies on the signal's efficacy. Such extensions would further enhance our understanding of EE's role in asset pricing and its practical applications in investment management.

**Figure 1:** Times series of EE percentiles and coverage.  
This figure plots descriptive statistics for EE. Panel A shows cross-sectional percentiles of EE over the sample. Panel B plots the monthly coverage of EE relative to the universe of CRSP stocks with available market capitalizations.

**Table 1:** Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on EE. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993b) three-factor model, Fama and French (1993b) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196606 to 202306.

**Table 2:** Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the EE strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993b) three-factor model, Fama and French (1993b) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196606 to 202306.

Panel A: Gross Returns and Alphas								
Portfolios	Breaks	Weights	$r^e$	$\alpha_{\text{CAPM}}$	$\alpha_{\text{FF3}}$	$\alpha_{\text{FF4}}$	$\alpha_{\text{FF5}}$	$\alpha_{\text{FF6}}$

**Table 3:** Conditional sort on size and EE

This table presents results for conditional double sorts on size and EE. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on EE. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high EE and short stocks with low EE. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 196606 to 202306.

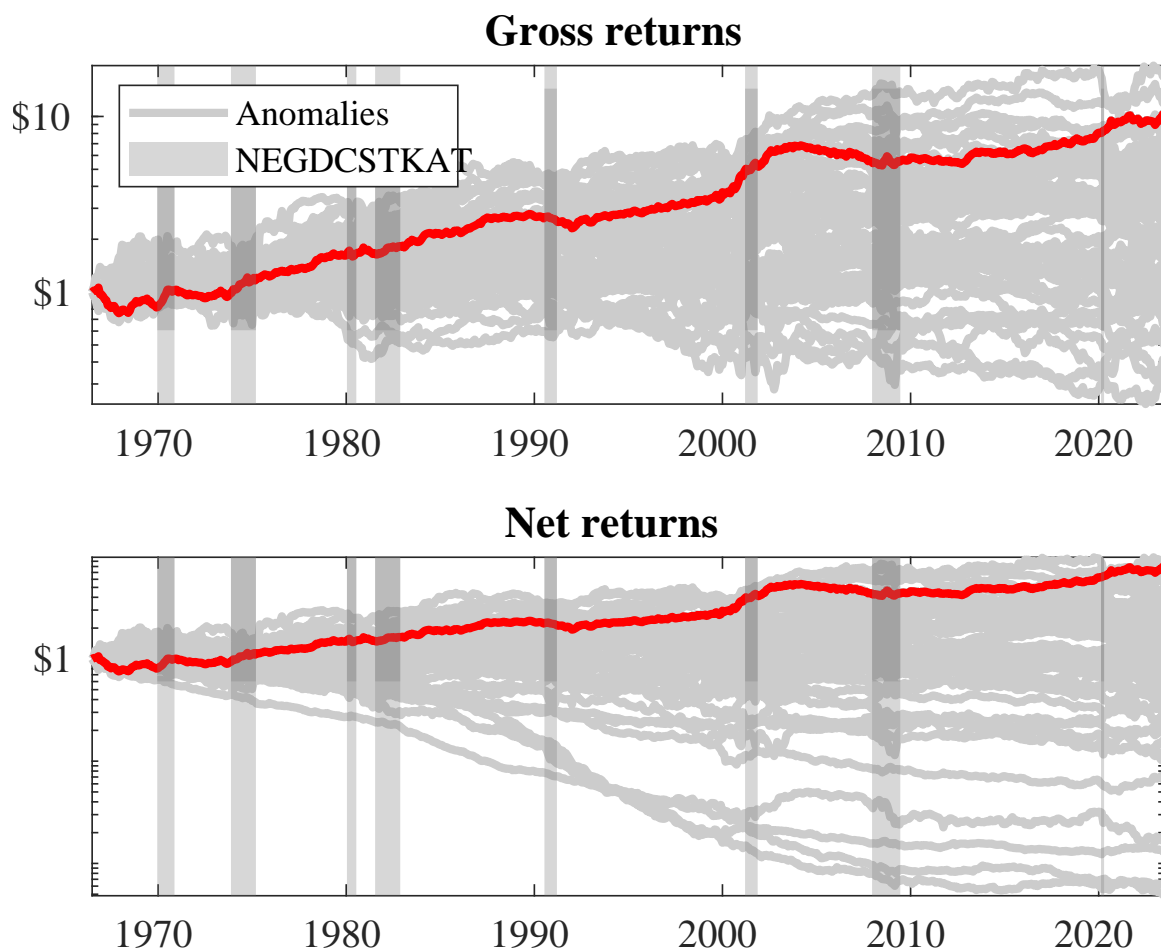

Panel A: portfolio average returns and time-series regression results												
Size quintiles	EE Quintiles					EE Strategies

**Figure 2:** Distribution of Sharpe ratios.

This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the EE with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

**Figure 3:** Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the EE trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

**Figure 4:** Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the EE trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, Fama and French (1993b) three-factor model, Fama and French (1993b) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). The left panel plots alphas with no adjustment for trading costs. The right panel plots Novy-Marx and Velikov (2016) net generalized alphas.

**Figure 5:** Distribution of correlations.

This figure plots a name histogram of correlations of 210 filtered anomaly signals with EE. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

**Figure 6:** Agglomerative hierarchical cluster plot

This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

**Figure 7:** Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of EE conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on  $\beta_{EE}$  from Fama-MacBeth regressions of the form  $r_{i,t} = \alpha + \beta_{EE}EE_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$ , where  $X$  stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on  $\alpha$  from spanning tests of the form:  $r_{EE,t} = \alpha + \beta r_{X,t} + \epsilon_t$ , where  $r_{X,t}$  stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on EE. Stocks are finally grouped into five EE portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted EE trading strategies conditioned on each of the 210 filtered anomalies.

**Table 4:** Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on EE. and the six most closely related anomalies. The regressions take the following form:  $r_{i,t} = \alpha + \beta_{EE} EE_{i,t} + \sum_{k=1}^s \beta_{X_k} X_{i,t}^k + \epsilon_{i,t}$ . The six most closely related anomalies,  $X$ , are Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

**Table 5:** Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the EE trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form:  $r_t^{EE} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$ , where  $X_k$  indicates each of the six most-closely related anomalies and  $f_j$  indicates the six factors from the [Fama and French \(2015\)](#) five-factor model augmented with the [Carhart \(1997\)](#) momentum factor. The six most closely related anomalies,  $X$ , are Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

**Figure 8:** Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following [Chen and Velikov \(2022\)](#). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as EE. Panel A shows results using "Average rank" as the combination method. See [Section 7](#) for details on the combination methods.
