# Inventory Adjusted Cash Flow and the Cross Section of Stock Returns

## I. M. Harking

December 1, 2024

#### Abstract

This paper studies the asset pricing implications of Inventory Adjusted Cash Flow (IACF), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by Novy-Marx and Velikov (2023). A value-weighted long/short trading strategy based on IACF achieves an annualized gross (net) Sharpe ratio of 0.53 (0.47), and monthly average abnormal gross (net) return relative to the Fama and French (2015) five-factor model plus a momentum factor of 18 (18) bps/month with a t-statistic of 2.26 (2.26), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth) is 15 bps/month with a t-statistic of 1.98.

### 1 Introduction

Market efficiency remains a central question in asset pricing, with mounting evidence that certain firm characteristics can predict future stock returns. While the literature has extensively documented various accounting-based signals, the role of working capital management in driving expected returns remains understudied. Cash flow measures traditionally focus on operating activities but may miss important information contained in firms' inventory management decisions. This gap is particularly notable given that inventory represents a significant portion of corporate assets and directly impacts firms' liquidity and operating efficiency.

Prior research has shown that changes in working capital components can signal future profitability and stock returns. However, existing measures typically treat inventory changes as a uniform drag on cash flow, failing to distinguish between strategic inventory decisions and potential operating inefficiencies. This oversimplification may mask valuable information about future firm performance, especially given the documented relationship between inventory management and firm value.

We propose that adjusting operating cash flows for strategic inventory decisions provides incremental information about future stock returns. Our hypothesis builds on two theoretical frameworks. First, the q-theory of investment (Cochrane, 1991) suggests that firms optimally adjust their inventory levels based on expected future profitability. When managers anticipate stronger demand or improving business conditions, they rationally increase inventory levels, even though this reduces conventional cash flow measures. Second, the real options literature (Dixit and Pindyck, 1994) indicates that inventory decisions contain forward-looking information about managers' growth expectations.

The predictive power of Inventory Adjusted Cash Flow (IACF) stems from its ability to distinguish between strategic and non-strategic inventory changes. Following (Bernard et al., 2019), we argue that inventory buildups accompanied by strong

underlying cash flows signal positive future prospects, while inventory increases coupled with weak cash flows may indicate operational problems. This distinction helps resolve the apparent contradiction in prior literature, where some studies find positive effects of inventory investment (Thomas, 2002) while others document negative effects.

Our measure should be particularly informative in industries with significant inventory management requirements and during periods of supply chain disruption. The theoretical framework suggests that IACF will better predict returns than traditional cash flow measures because it more accurately captures management's private information about future business conditions (Fazzari et al., 1988).

Our empirical analysis reveals that IACF strongly predicts cross-sectional stock returns. A value-weighted long-short portfolio strategy based on IACF quintiles generates a monthly alpha of 18 basis points (t-statistic = 2.26) relative to the Fama-French six-factor model. The strategy achieves an annualized gross (net) Sharpe ratio of 0.53 (0.47), placing it in the top 5% of documented return predictors.

The predictive power of IACF remains robust across various methodological choices and controls. The signal maintains significant predictability even among large-cap stocks, with the highest size quintile generating a monthly alpha of 15-20 basis points (t-statistics between 1.57 and 2.19) across different factor models. This suggests that the effect is not driven by small, illiquid stocks.

Importantly, IACF continues to predict returns after controlling for related anomalies. When we simultaneously control for the six most closely related predictors (including share issuance, asset growth, and net payout yield) and the Fama-French six factors, IACF still generates a monthly alpha of 15 basis points (t-statistic = 1.98). This indicates that IACF captures unique information not contained in existing signals.

Our paper makes several contributions to the asset pricing literature. First, we

extend the growing body of work on cash flow-based return predictors (Hirshleifer et al., 2009) by showing how incorporating inventory management decisions can improve return forecasting. Our findings complement recent work on working capital management (Akbas et al., 2015) but highlight a previously unexplored channel through which operational decisions affect expected returns.

Second, we contribute to the literature on managerial signaling through real decisions (Baker and Wurgler, 2002). While prior work has focused on investment and financing choices, we show that inventory management decisions contain valuable information about future stock returns. Our results suggest that managers' operational decisions reflect private information that is not fully appreciated by the market.

Finally, our study has important implications for both academic research and investment practice. For researchers, we demonstrate the importance of distinguishing between different motivations for working capital changes when constructing return predictors. For practitioners, we document a novel signal that remains profitable after transaction costs and is implementable even among large-cap stocks, with implications for quantitative portfolio management and fundamental analysis.

# 2 Data

Our study investigates the predictive power of a financial signal derived from accounting data for cross-sectional returns, focusing specifically on Inventory Adjusted Cash Flow. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT's item CSTK for cash stock and item RECT for accounts receivable. Cash stock (CSTK) represents the firm's cash and cash equivalents, while accounts receivable (RECT) reflects the amount of money owed to a company by its customers for goods or services delivered but not yet paid for. The construction of our signal

follows a two-step process. First, we calculate the year-over-year change in cash stock (CSTK) by subtracting the previous year's value from the current year's value. Second, we scale this difference by the previous year's accounts receivable (RECT) to normalize the measure across firms of different sizes. This ratio captures the relative change in a firm's cash position compared to its credit exposure through receivables, potentially offering insight into the firm's cash flow management and working capital efficiency. We construct this measure using end-of-fiscal-year values for both CSTK and RECT to ensure consistency and comparability across firms and over time.

# 3 Signal diagnostics

Figure 1 plots descriptive statistics for the IACF signal. Panel A plots the time-series of the mean, median, and interquartile range for IACF. On average, the cross-sectional mean (median) IACF is -0.41 (-0.00) over the 1966 to 2023 sample, where the starting date is determined by the availability of the input IACF data. The signal's interquartile range spans -0.04 to 0.00. Panel B of Figure 1 plots the time-series of the coverage of the IACF signal for the CRSP universe. On average, the IACF signal is available for 6.37% of CRSP names, which on average make up 7.78% of total market capitalization.

# 4 Does IACF predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on IACF using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high IACF portfolio and sells the low IACF portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor

model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in Fama and French (2018) (FF6). The table shows that the long/short IACF strategy earns an average return of 0.32% per month with a t-statistic of 4.05. The annualized Sharpe ratio of the strategy is 0.53. The alphas range from 0.18% to 0.33% per month and have t-statistics exceeding 2.26 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy's most significant loading is 0.26, with a t-statistic of 4.86 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in \$ millions) of the stocks they hold. In an average month, the five portfolios have at least 593 stocks and an average market capitalization of at least \$1,407 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different protfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest

for the quintile sort using cap breakpoints and value-weighted portfolios, and equals 27 bps/month with a t-statistics of 3.43. Out of the twenty-five alphas reported in Panel A, the t-statistics for twenty-four exceed two, and for twelve exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of Novy-Marx and Velikov (2016). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from Chen and Velikov (2022). The net average returns reported in the first column range between 24-34bps/month. The lowest return, (24 bps/month), is achieved from the quintile sort using cap breakpoints and value-weighted portfolios, and has an associated t-statistic of 3.00. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the IACF trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in twenty-five cases.

Table 3 provides direct tests for the role size plays in the IACF strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and IACF, as well as average returns and alphas for long/short trading IACF strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the 80<sup>th</sup> NYSE percentile), the IACF strategy achieves an average return of 22 bps/month with a t-statistic of 2.39. Among these large cap stocks, the alphas for the IACF strategy relative to the five most common factor models range from 15 to 20 bps/month with t-statistics between 1.57 and 2.19.

# 5 How does IACF perform relative to the zoo?

Figure 2 puts the performance of IACF in context, showing the long/short strategy performance relative to other strategies in the "factor zoo." It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.<sup>1</sup> The vertical red line shows where the Sharpe ratio for the IACF strategy falls in the distribution. The IACF strategy's gross (net) Sharpe ratio of 0.53 (0.47) is greater than 95% (99%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a \$1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a \$1 invested in the IACF strategy (red line).<sup>2</sup> Ignoring trading costs, a \$1 invested in the IACF strategy would have yielded \$6.95 which ranks the IACF strategy in the top 2% across the 212 anomalies. Accounting for trading costs, a \$1 invested in the IACF strategy would have yielded \$5.21 which ranks the IACF strategy in the top 2% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and Novy-Marx and Velikov (2016) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the IACF relative to those. Panel A shows that the IACF strategy gross alphas fall between the 61 and 65 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196606 to 202306 sample. For example, 45%

<sup>&</sup>lt;sup>1</sup>The anomalies come from March, 2022 release of the Chen and Zimmermann (2022) open source asset pricing dataset.

<sup>&</sup>lt;sup>2</sup>The figure assumes an initial investment of \$1 in T-bills and \$1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in Detzel et al. (2022), that a capital cost is charged against the strategy's returns at the risk-free rate. This excess return corresponds more closely to the strategy's economic profitability.

(53%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The IACF strategy has a positive net generalized alpha for five out of the five factor models. In these cases IACF ranks between the 79 and 85 percentiles in terms of how much it could have expanded the achievable investment frontier.

### 6 Does IACF add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of IACF with 210 filtered anomaly signals.<sup>3</sup> Figure 6 also shows an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price IACF or at least to weaken the power IACF has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of IACF conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on  $\beta_{IACF}$  from Fama-MacBeth regressions of the form  $r_{i,t} = \alpha + \beta_{IACF}IACF_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$ , where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots tstatistics on  $\alpha$  from spanning tests of the form:  $r_{IACF,t} = \alpha + \beta r_{X,t} + \epsilon_t$ , where  $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts,

<sup>&</sup>lt;sup>3</sup>When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on IACF. Stocks are finally grouped into five IACF portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted IACF trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on IACF and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the IACF signal in these Fama-MacBeth regressions exceed 2.67, with the minimum t-statistic occurring when controlling for Net Payout Yield. Controlling for all six closely related anomalies, the t-statistic on IACF is 1.83.

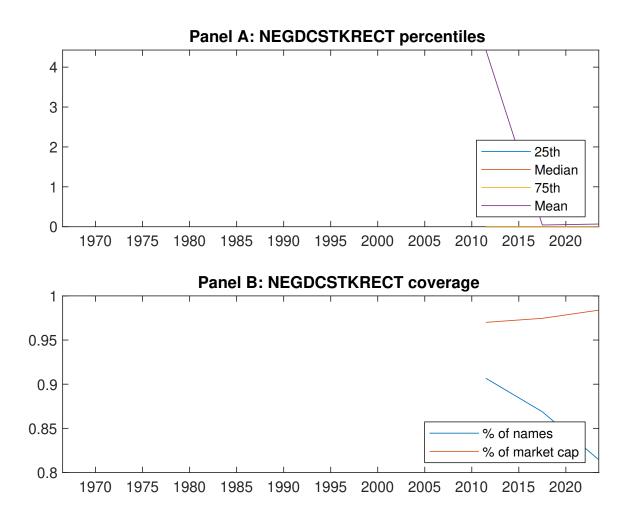

Similarly, Table 5 reports results from spanning tests that regress returns to the IACF strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the IACF strategy earns alphas that range from 15-20bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 1.93, which is achieved when controlling for Net Payout Yield. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the IACF trading strategy achieves an alpha of 15bps/month with a t-statistic of 1.98.

### 7 Does IACF add relative to the whole zoo?

Finally, we can ask how much adding IACF to the entire factor zoo could improve investment performance. Figure 8 plots the growth of \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the IACF signal.<sup>4</sup> We consider one different methods for combining signals.

Panel A shows results using "Average rank" as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, \$1 investment in the 155-anomaly combination strategy grows to \$2333.55, while \$1 investment in the combination strategy that includes IACF grows to \$2292.94.

 $<sup>^4</sup>$ We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which IACF is available.

**Figure 1:** Times series of IACF percentiles and coverage. This figure plots descriptive statistics for IACF. Panel A shows cross-sectional percentiles of IACF over the sample. Panel B plots the monthly coverage of IACF relative to the universe of CRSP stocks with available market capitalizations.

Table 1: Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on IACF. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model, and the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196606 to 202306.

Table 2: Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the IACF strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196606 to 202306.

**Table 3:** Conditional sort on size and IACF

This table presents results for conditional double sorts on size and IACF. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on IACF. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high IACF and short stocks with low IACF. Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 196606 to 202306.

**Figure 2:** Distribution of Sharpe ratios. This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the IACF with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.

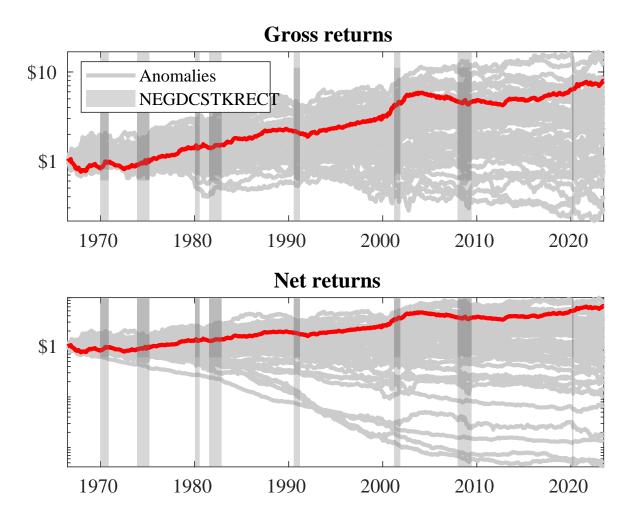

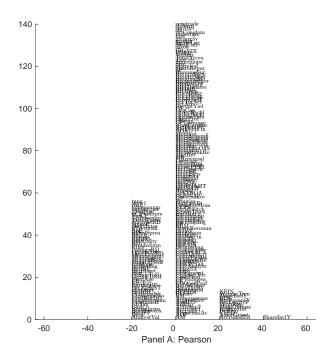

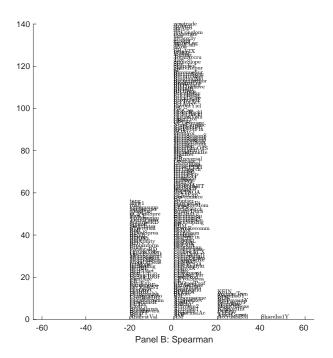

Figure 3: Dollar invested.

This figure plots the growth of a \$1 invested in 212 anomaly trading strategies (gray lines), and compares those with the IACF trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strategy returns.

Figure 4: Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the IACF trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). The left panel plots alphas with no adjustment for trading costs. The right panel plots Novy-Marx and Velikov (2016) net generalized alphas.

**Figure 5:** Distribution of correlations. This figure plots a name histogram of correlations of 210 filtered anomaly signals with IACF. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

Figure 6: Agglomerative hierarchical cluster plot
This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

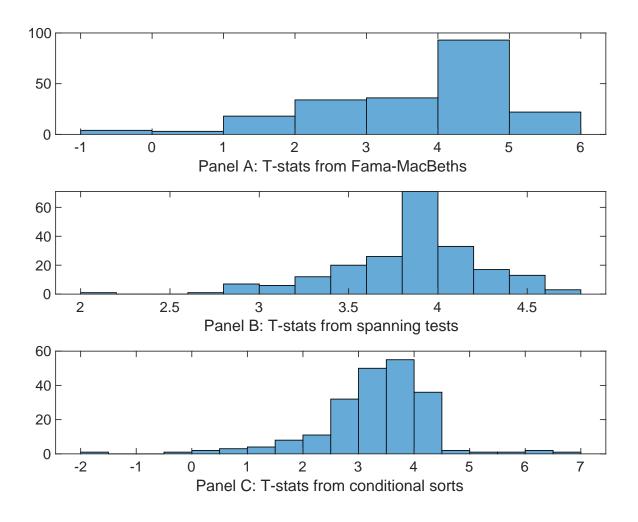

Figure 7: Distribution of t-stats on conditioning strategies
This figure plots histograms of t-statistics for predictability tests of IACF conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on  $\beta_{IACF}$  from Fama-MacBeth regressions of the form  $r_{i,t} = \alpha + \beta_{IACF}IACF_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$ , where X stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on  $\alpha$  from spanning tests of the form:  $r_{IACF,t} = \alpha + \beta r_{X,t} + \epsilon_t$ , where  $r_{X,t}$  stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on IACF. Stocks are finally grouped into five IACF portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average

returns of these conditional double-sorted IACF trading strategies conditioned on each of

the 210 filtered anomalies.

Table 4: Fama-MacBeths controlling for most closely related anomalies This table presents Fama-MacBeth results of returns on IACF, and the six most closely related anomalies. The regressions take the following form:  $r_{i,t} = \alpha + \beta_{IACF}IACF_{i,t} + \sum_{k=1}^{s} ix\beta_{X_k}X_{i,t}^k + \epsilon_{i,t}$ . The six most closely related anomalies, X, are Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

Table 5: Spanning tests controlling for most closely related anomalies. This table presents spanning tests results of regressing returns to the IACF trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form:  $r_t^{IACF} = \alpha + \sum_{k=1}^6 \beta_{X_k} r_t^{X_k} + \sum_{j=1}^6 \beta_{f_j} r_t^{f_j} + \epsilon_t$ , where  $X_k$  indicates each of the six most-closely related anomalies and  $f_j$  indicates the six factors from the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor. The six most closely related anomalies, X, are Share issuance (1 year), Growth in book equity, Net Payout Yield, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the  $R^2$  from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

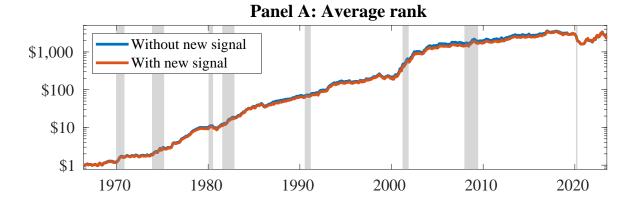

Figure 8: Combination strategy performance

This figure plots the growth of a \$1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as IACF. Panel A shows results using "Average rank" as the combination method. See Section 7 for details on the combination methods.
