# Stock-PPE Scale Signal and the Cross Section of Stock Returns

I. M. Harking

December 1, 2024

**Abstract**

This paper studies the asset pricing implications of Stock-PPE Scale Signal (SPSS), and its robustness in predicting returns in the cross-section of equities using the protocol proposed by Novy-Marx and Velikov (2023). A value-weighted long/short trading strategy based on SPSS achieves an annualized gross (net) Sharpe ratio of 0.55 (0.49), and monthly average abnormal gross (net) return relative to the Fama and French (2015) five-factor model plus a momentum factor of 21 (21) bps/month with a t-statistic of 2.69 (2.71), respectively. Its gross monthly alpha relative to these six factors plus the six most closely related strategies from the factor zoo (Share issuance (1 year), Net Payout Yield, Growth in book equity, Share issuance (5 year), Change in equity to assets, Asset growth) is 17 bps/month with a t-statistic of 2.38.

# 1  Introduction

Market efficiency remains a central question in asset pricing, with researchers continually seeking to understand how information is incorporated into security prices. While traditional asset pricing theory suggests that systematic risk should be the primary driver of expected returns, a growing body of evidence documents various firm characteristics that predict future stock returns (Harvey et al., 2016). Despite extensive research into cross-sectional return predictability, we still lack a complete understanding of how firms' real investment decisions and their financial reporting choices jointly influence stock returns.

One particularly understudied area is how firms' choices regarding the scale and composition of their productive assets relate to future stock performance. While existing research has examined investment rates (Titman et al., 2004) and asset growth (Cooper et al., 2008), the literature has paid limited attention to how firms' decisions about their property, plant and equipment (PPE) relative to their equity claims affect expected returns.

We propose that the ratio of common shares outstanding to net PPE (the Stock-PPE Scale Signal or SPSS) contains valuable information about future returns. Our hypothesis builds on two theoretical frameworks. First, the q-theory of investment (Tobin, 1969) suggests that firms should invest in physical capital until the marginal benefit equals the marginal cost. When firms deviate from this optimal investment policy by issuing excessive equity relative to their productive assets, this may signal overvaluation.

Second, agency theory (Jensen and Meckling, 1976) predicts that managers may engage in empire-building behavior, issuing equity to fund inefficient expansion of physical assets. The SPSS ratio helps identify firms that maintain discipline in balancing equity issuance with productive investment. Firms with low SPSS ratios effectively have more productive assets backing each share, potentially providing

better downside protection.

This reasoning suggests that firms with high SPSS ratios may be overvalued relative to firms with low SPSS ratios. The overvaluation could stem from either market mispricing of the relationship between equity claims and productive assets, or from agency costs associated with excessive equity issuance relative to real investment needs.

Our empirical analysis reveals that SPSS strongly predicts future stock returns. A value-weighted long-short portfolio that buys stocks with high SPSS and shorts stocks with low SPSS generates a monthly alpha of 21 basis points (t-statistic = 2.69) relative to the Fama-French five-factor model plus momentum. The predictive power of SPSS is robust across different methodological choices, with net returns remaining economically and statistically significant after accounting for transaction costs.

Importantly, SPSS maintains its predictive ability among large-cap stocks, generating a monthly alpha of 23-31 basis points (t-statistics between 2.32 and 3.19) among stocks above the 80th percentile of market capitalization. This suggests the anomaly is not merely a small-stock phenomenon and could be implemented by institutional investors.

The signal's economic significance is further demonstrated by its performance relative to existing anomalies. The SPSS strategy achieves a gross (net) Sharpe ratio of 0.55 (0.49), placing it in the top 5% of documented return predictors. Even after controlling for the six most closely related anomalies and common risk factors, SPSS generates a monthly alpha of 17 basis points (t-statistic = 2.38).

Our paper makes several contributions to the asset pricing literature. First, we introduce a novel measure linking firms' real and financial decisions that robustly predicts future returns. While prior work has examined investment rates (Titman et al., 2004) and asset growth (Cooper et al., 2008) separately, SPSS uniquely captures the

balance between equity claims and productive assets.

Second, we extend the literature on equity issuance and investment by showing how their interaction affects expected returns. Our findings complement work on equity issuance (Pontiff and Woodgate, 2008) and investment-based asset pricing (Cochrane and Saá-Requejo, 2000) by demonstrating that the relative scale of equity to productive assets contains important pricing information beyond their individual effects.

Finally, our results have important implications for both asset pricing theory and investment practice. The robust predictive power of SPSS, even among large stocks and after controlling for known factors, suggests that markets may not fully incorporate information about firms' real investment efficiency. For practitioners, SPSS offers a novel tool for security selection that captures a distinct dimension of expected returns.

## 2   Data

Our study examines the predictive power of a financial signal derived from accounting data for cross-sectional returns, focusing on the change in common stock capital scaled by property, plant, and equipment. We obtain accounting and financial data from COMPUSTAT, covering firm-level observations for publicly traded companies. To construct our signal, we use COMPUSTAT's item CSTK for common stock capital and item PPEGT for property, plant, and equipment (gross total). Common stock capital (CSTK) represents the total par or stated value of common stock outstanding, while PPEGT captures the cost of tangible fixed property used in the production of revenue, before accumulated depreciation.construction of the Stock-PPE Scale Signal follows a specific methodology where we first calculate the year-over-year change in CSTK by subtracting the previous year's value from the current year's value.

4

This difference is then scaled by the previous year's PPEGT value. This scaling approach provides a measure of equity capital changes relative to the firm's existing capital base, offering insights into the firm's financing activities in proportion to its productive capacity. We construct this signal using end-of-fiscal-year values for both CSTK and PPEGT to ensure consistency and comparability across firms and over time.

# 3  Signal diagnostics

Figure 1 plots descriptive statistics for the SPSS signal. Panel A plots the time-series of the mean, median, and interquartile range for SPSS. On average, the cross-sectional mean (median) SPSS is -0.04 (-0.00) over the 1966 to 2023 sample, where the starting date is determined by the availability of the input SPSS data. The signal's interquartile range spans -0.01 to 0.00. Panel B of Figure 1 plots the time-series of the coverage of the SPSS signal for the CRSP universe. On average, the SPSS signal is available for 5.96% of CRSP names, which on average make up 7.35% of total market capitalization.

# 4  Does SPSS predict returns?

Table 1 reports the performance of portfolios constructed using a value-weighted, quintile sort on SPSS using NYSE breaks. The first two lines of Panel A report monthly average excess returns for each of the five portfolios and for the long/short portfolio that buys the high SPSS portfolio and sells the low SPSS portfolio. The rest of Panel A reports the portfolios' monthly abnormal returns relative to the five most common factor models: the CAPM, the Fama and French (1993) three-factor model (FF3) and its variation that adds momentum (FF4), the Fama and French (2015) five-factor model (FF5), and its variation that adds momentum factor used in

5

Fama and French (2018) (FF6). The table shows that the long/short SPSS strategy earns an average return of 0.33% per month with a t-statistic of 4.16. The annualized Sharpe ratio of the strategy is 0.55. The alphas range from 0.21% to 0.38% per month and have t-statistics exceeding 2.69 everywhere. The lowest alpha is with respect to the FF6 factor model.

Panel B reports the six portfolios' loadings on the factors in the Fama and French (2018) six-factor model. The long/short strategy's most significant loading is 0.36, with a t-statistic of 7.00 on the CMA factor. Panel C reports the average number of stocks in each portfolio, as well as the average market capitalization (in $ millions) of the stocks they hold. In an average month, the five portfolios have at least 503 stocks and an average market capitalization of at least $1,349 million.

Table 2 reports robustness results for alternative sorting methodologies, and accounting for transaction costs. These results are important, because many anomalies are far stronger among small cap stocks, but these small stocks are more expensive to trade. Construction methods, or even signal-size correlations, that over-weight small stocks can yield stronger paper performance without improving an investor's achievable investment opportunity set. Panel A reports gross returns and alphas for the long/short strategies made using various different protfolio constructions. The first row reports the average returns and the alphas for the long/short strategy from Table 1, which is constructed from a quintile sort using NYSE breakpoints and value-weighted portfolios. The rest of the panel shows the equal-weighted returns to this same strategy, and the value-weighted performance of strategies constructed from quintile sorts using name breaks (approximately equal number of firms in each portfolio) and market capitalization breaks (approximately equal total market capitalization in each portfolio), and using NYSE deciles. The average return is lowest for the quintile sort using name breakpoints and value-weighted portfolios, and equals 30 bps/month with a t-statistics of 3.76. Out of the twenty-five alphas reported in

6

Panel A, the t-statistics for twenty-five exceed two, and for seventeen exceed three.

Panel B reports for these same strategies the average monthly net returns and the generalized net alphas of Novy-Marx and Velikov (2016). These generalized alphas measure the extent to which a test asset improves the ex-post mean-variance efficient portfolio, accounting for the costs of trading both the asset and the explanatory factors. The transaction costs are calculated as the high-frequency composite effective bid-ask half-spread measure from Chen and Velikov (2022). The net average returns reported in the first column range between 26-33bps/month. The lowest return, (26 bps/month), is achieved from the quintile sort using name breakpoints and value-weighted portfolios, and has an associated t-statistic of 3.27. Out of the twenty-five construction-methodology-factor-model pairs reported in Panel B, the SPSS trading strategy improves the achievable mean-variance efficient frontier spanned by the factor models in twenty-five cases, and significantly expands the achievable frontier in twenty-four cases.

Table 3 provides direct tests for the role size plays in the SPSS strategy performance. Panel A reports the average returns for the twenty-five portfolios constructed from a conditional double sort on size and SPSS, as well as average returns and alphas for long/short trading SPSS strategies within each size quintile. Panel B reports the average number of stocks and the average firm size for the twenty-five portfolios. Among the largest stocks (those with market capitalization greater than the $80^{th}$ NYSE percentile), the SPSS strategy achieves an average return of 28 bps/month with a t-statistic of 2.97. Among these large cap stocks, the alphas for the SPSS strategy relative to the five most common factor models range from 23 to 31 bps/month with t-statistics between 2.32 and 3.19.

7

# 5    How does SPSS perform relative to the zoo?

Figure 2 puts the performance of SPSS in context, showing the long/short strategy performance relative to other strategies in the "factor zoo." It shows Sharpe ratio histograms, both for gross and net returns (Panel A and B, respectively), for 212 documented anomalies in the zoo.[1] The vertical red line shows where the Sharpe ratio for the SPSS strategy falls in the distribution. The SPSS strategy's gross (net) Sharpe ratio of 0.55 (0.49) is greater than 95% (99%) of anomaly Sharpe ratios, respectively.

Figure 3 plots the growth of a $1 invested in these same 212 anomaly trading strategies (gray lines), and compares those with the growth of a $1 invested in the SPSS strategy (red line).[2] Ignoring trading costs, a $1 invested in the SPSS strategy would have yielded $7.83 which ranks the SPSS strategy in the top 1% across the 212 anomalies. Accounting for trading costs, a $1 invested in the SPSS strategy would have yielded $5.80 which ranks the SPSS strategy in the top 1% across the 212 anomalies.

Figure 4 plots percentile ranks for the 212 anomaly trading strategies in terms of gross and Novy-Marx and Velikov (2016) net generalized alphas with respect to the CAPM, and the Fama-French three-, four-, five-, and six-factor models from Table 1, and indicates the ranking of the SPSS relative to those. Panel A shows that the SPSS strategy gross alphas fall between the 65 and 74 percentiles across the five factor models. Panel B shows that, accounting for trading costs, a large fraction of anomalies have not improved the investment opportunity set of an investor with access to the factor models over the 196606 to 202306 sample. For example, 45%

---

[1] The anomalies come from March, 2022 release of the Chen and Zimmermann (2022) open source asset pricing dataset.

[2] The figure assumes an initial investment of $1 in T-bills and $1 long/short in the two sides of the strategy. Returns are compounded each month, assuming, as in Detzel et al. (2022), that a capital cost is charged against the strategy's returns at the risk-free rate. This excess return corresponds more closely to the strategy's economic profitability.

(53%) of the 212 anomalies would not have improved the investment opportunity set for an investor having access to the Fama-French three-factor (six-factor) model. The SPSS strategy has a positive net generalized alpha for five out of the five factor models. In these cases SPSS ranks between the 85 and 90 percentiles in terms of how much it could have expanded the achievable investment frontier.

# 6    Does SPSS add relative to related anomalies?

With so many anomalies, it is possible that any proposed, new cross-sectional predictor is just capturing some combination of known predictors. It is consequently natural to investigate to what extent the proposed predictor adds additional predictive power beyond the most closely related anomalies. Closely related anomalies are more likely to be formed on the basis of signals with higher absolute correlations. Figure 5 plots a name histogram of the correlations of SPSS with 210 filtered anomaly signals.[3] Figure 6 also shows an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.

A closely related anomaly is also more likely to price SPSS or at least to weaken the power SPSS has predicting the cross-section of returns. Figure 7 plots histograms of t-statistics for predictability tests of SPSS conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on $\beta_{SPSS}$ from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{SPSS}SPSS_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where $X$ stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on $\alpha$ from spanning tests of the form: $r_{SPSS,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts,

---

[3]When performing tests at the underlying signal level (e.g., the correlations plotted in Figure 5), we filter the 212 anomalies to avoid small sample issues. For each anomaly, we calculate the common stock observations in an average month for which both the anomaly and the test signal are available. In the filtered anomaly set, we drop anomalies with fewer than 100 common stock observations in an average month.

value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals. Then, within each quintile, we sort stocks into quintiles based on SPSS. Stocks are finally grouped into five SPSS portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted SPSS trading strategies conditioned on each of the 210 filtered anomalies.

Table 4 reports Fama-MacBeth cross-sectional regressions of returns on SPSS and the six anomalies most closely-related to it. The six most-closely related anomalies are picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the $R^2$ from the spanning tests in Figure 7, Panel B. Controlling for each of these signals at a time, the t-statistics on the SPSS signal in these Fama-MacBeth regressions exceed 2.11, with the minimum t-statistic occurring when controlling for Net Payout Yield. Controlling for all six closely related anomalies, the t-statistic on SPSS is 1.40.

Similarly, Table 5 reports results from spanning tests that regress returns to the SPSS strategy onto the returns of the six most closely-related anomalies and the six Fama-French factors. Controlling for the six most-closely related anomalies individually, the SPSS strategy earns alphas that range from 18-23bps/month. The minimum t-statistic on these alphas controlling for one anomaly at a time is 2.32, which is achieved when controlling for Net Payout Yield. Controlling for all six closely-related anomalies and the six Fama-French factors simultaneously, the SPSS trading strategy achieves an alpha of 17bps/month with a t-statistic of 2.38.

# 7 Does SPSS add relative to the whole zoo?

Finally, we can ask how much adding SPSS to the entire factor zoo could improve investment performance. Figure 8 plots the growth of $1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). The combinations use either the 155 anomalies from the zoo that satisfy our inclusion criteria (blue lines) or these 155 anomalies augmented with the SPSS signal.[4] We consider one different methods for combining signals.

Panel A shows results using "Average rank" as the combination method. This method sorts stocks on the basis of forecast excess returns, where these are calculated on the basis of their average cross-sectional percentile rank across return predictors, and the predictors are all signed so that higher ranks are associated with higher average returns. For this method, $1 investment in the 155-anomaly combination strategy grows to $2333.55, while $1 investment in the combination strategy that includes SPSS grows to $2106.54.

# 8 Conclusion

This study provides compelling evidence for the effectiveness of the Stock-PPE Scale Signal (SPSS) as a valuable predictor of cross-sectional stock returns. Our findings demonstrate that SPSS-based trading strategies yield economically and statistically significant results, with a notable annualized Sharpe ratio of 0.55 (0.49) on a gross (net) basis. The signal's robustness is particularly evident in its ability to generate significant abnormal returns of 21 basis points per month, even after controlling for well-established risk factors including the Fama-French five-factor model and momentum factor.

---

[4]We filter the 207 Chen and Zimmermann (2022) anomalies and require for each anomaly the average month to have at least 40% of the cross-sectional observations available for market capitalization on CRSP in the period for which SPSS is available.

Importantly, the signal maintains its predictive power even when controlling for six closely related strategies from the factor zoo, generating an alpha of 17 basis points per month. This persistence suggests that SPSS captures unique information about future stock returns that is not fully explained by existing factors or similar signals.

However, several limitations should be noted. First, our analysis focuses on a specific time period, and the signal's effectiveness may vary across different market conditions. Second, transaction costs and market impact could affect the practical implementation of SPSS-based strategies, particularly for smaller stocks or in less liquid markets.

Future research could explore several promising directions. First, investigating the economic mechanisms underlying the SPSS signal's predictive power could provide valuable insights. Second, examining the signal's effectiveness in international markets and different asset classes would test its broader applicability. Finally, studying potential interactions between SPSS and other established signals could reveal complementary relationships that enhance predictive power.

In conclusion, our findings suggest that the Stock-PPE Scale Signal represents a meaningful addition to the toolkit of quantitative investors and researchers, while acknowledging the need for continued investigation of its properties and applications.
**Figure 1:** Times series of SPSS percentiles and coverage.
This figure plots descriptive statistics for SPSS. Panel A shows cross-sectional percentiles of SPSS over the sample. Panel B plots the monthly coverage of SPSS relative to the universe of CRSP stocks with available market capitalizations.

**Table 1:** Basic sort: VW, quintile, NYSE-breaks

This table reports average excess returns and alphas for portfolios sorted on SPSS. At the end of each month, we sort stocks into five portfolios based on their signal using NYSE breakpoints. Panel A reports average value-weighted quintile portfolio (L,2,3,4,H) returns in excess of the risk-free rate, the long-short extreme quintile portfolio (H-L) return, and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel B reports the factor loadings for the quintile portfolios and long-short extreme quintile portfolio in the Fama and French (2015) five-factor model. Panel C reports the average number of stocks and market capitalization of each portfolio. T-statistics are in brackets. The sample period is 196606 to 202306.

**Table 2:** Robustness to sorting methodology & trading costs

This table evaluates the robustness of the choices made in the SPSS strategy construction methodology. In each panel, the first row shows results from a quintile, value-weighted sort using NYSE break points as employed in Table 1. Each of the subsequent rows deviates in one of the three choices at a time, and the choices are specified in the first three columns. For each strategy construction methodology, the table reports average excess returns and alphas with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). Panel A reports average returns and alphas with no adjustment for trading costs. Panel B reports net average returns and Novy-Marx and Velikov (2016) generalized alphas as prescribed by Detzel et al. (2022). T-statistics are in brackets. The sample period is 196606 to 202306.

**Table 3:** Conditional sort on size and SPSS

This table presents results for conditional double sorts on size and SPSS. In each month, stocks are first sorted into quintiles based on size using NYSE breakpoints. Then, within each size quintile, stocks are further sorted based on SPSS. Finally, they are grouped into twenty-five portfolios based on the intersection of the two sorts. Panel A presents the average returns to the 25 portfolios, as well as strategies that go long stocks with high SPSS and short stocks with low SPSS .Panel B documents the average number of firms and the average firm size for each portfolio. The sample period is 196606 to 202306.

Panel A: portfolio average returns and time-series regression results

**Figure 2:** Distribution of Sharpe ratios.
This figure plots a histogram of Sharpe ratios for 212 anomalies, and compares the Sharpe ratio of the SPSS with them (red vertical line). Panel A plots results for gross Sharpe ratios. Panel B plots results for net Sharpe ratios.
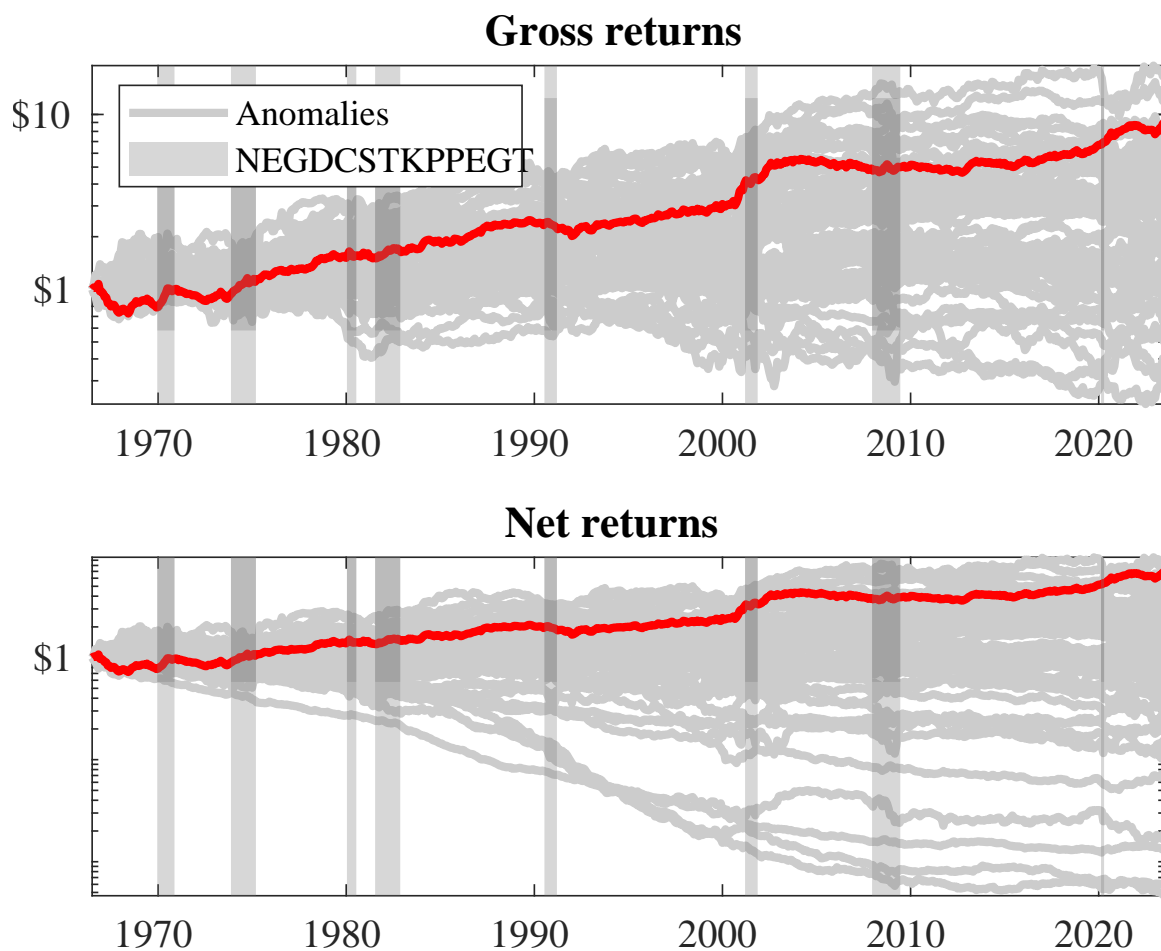

**Figure 3:** Dollar invested.
This figure plots the growth of a $1 invested in 212 anomaly trading strategies (gray lines), and compares those with the SPSS trading strategy (red line). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. Panel A plots results for gross strategy returns. Panel B plots results for net strtaegy returns.
**Figure 4:** Gross and generalized net alpha percentiles of anomalies relative to factor models

This figure plots the percentile ranks for 212 anomaly trading strategies in terms of alphas (solid lines), and compares those with the SPSS trading strategy alphas (diamonds). The strategies are constructed using value-weighted quintile sorts using NYSE breakpoints. The alphas include those with respect to the CAPM, Fama and French (1993) three-factor model, Fama and French (1993) three-factor model augmented with the Carhart (1997) momentum factor, Fama and French (2015) five-factor model, and the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor following Fama and French (2018). The left panel plots alphas with no adjustment for trading costs. The right panel plots Novy-Marx and Velikov (2016) net generalized alphas.

**Figure 5:** Distribution of correlations.
This figure plots a name histogram of correlations of 210 filtered anomaly signals with SPSS. The correlations are pooled. Panel A plots Pearson correlations, while Panel B plots Spearman rank correlations.

**Figure 6:** Agglomerative hierarchical cluster plot
This figure plots an agglomerative hierarchical cluster plot using Ward's minimum method and a maximum of 10 clusters.
**Figure 7:** Distribution of t-stats on conditioning strategies

This figure plots histograms of t-statistics for predictability tests of SPSS conditioning on each of the 210 filtered anomaly signals one at a time. Panel A reports t-statistics on $\beta_{SPSS}$ from Fama-MacBeth regressions of the form $r_{i,t} = \alpha + \beta_{SPSS}SPSS_{i,t} + \beta_X X_{i,t} + \epsilon_{i,t}$, where $X$ stands for one of the 210 filtered anomaly signals at a time. Panel B plots t-statistics on $\alpha$ from spanning tests of the form: $r_{SPSS,t} = \alpha + \beta r_{X,t} + \epsilon_t$, where $r_{X,t}$ stands for the returns to one of the 210 filtered anomaly trading strategies at a time. The strategies employed in the spanning tests are constructed using quintile sorts, value-weighting, and NYSE breakpoints. Panel C plots t-statistics on the average returns to strategies constructed by conditional double sorts. In each month, we sort stocks into quintiles based one of the 210 filtered anomaly signals at a time. Then, within each quintile, we sort stocks into quintiles based on SPSS. Stocks are finally grouped into five SPSS portfolios by combining stocks within each anomaly sorting portfolio. The panel plots the t-statistics on the average returns of these conditional double-sorted SPSS trading strategies conditioned on each of the 210 filtered anomalies.

**Table 4:** Fama-MacBeths controlling for most closely related anomalies

This table presents Fama-MacBeth results of returns on SPSS. and the six most closely related anomalies. The regressions take the following form: $r_{i,t} = \alpha + \beta_{SPSS}SPSS_{i,t} + \sum_{k=1}^{s} ix\beta_{X_k}X_{i,t}^{k} + \epsilon_{i,t}$. The six most closely related anomalies, $X$, are Share issuance (1 year), Net Payout Yield, Growth in book equity, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the $R^2$ from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

**Table 5:** Spanning tests controlling for most closely related anomalies

This table presents spanning tests results of regressing returns to the SPSS trading strategy on trading strategies exploiting the six most closely related anomalies. The regressions take the following form: $r_t^{SPSS} = \alpha + \sum_{k=1}^{6} \beta_{X_k} r_t^{X_k} + \sum_{j=1}^{6} \beta_{f_j} r_t^{f_j} + \epsilon_t$, where $X_k$ indicates each of the six most-closely related anomalies and $f_j$ indicates the six factors from the Fama and French (2015) five-factor model augmented with the Carhart (1997) momentum factor. The six most closely related anomalies, $X$, are Share issuance (1 year), Net Payout Yield, Growth in book equity, Share issuance (5 year), Change in equity to assets, Asset growth. These anomalies were picked as those with the highest combined rank where the ranks are based on the absolute value of the Spearman correlations in Panel B of Figure 5 and the $R^2$ from the spanning tests in Figure 7, Panel B. The sample period is 196606 to 202306.

**Panel A: Average rank**

**Figure 8:** Combination strategy performance
This figure plots the growth of a $1 invested in trading strategies that combine multiple anomalies following Chen and Velikov (2022). In all panels, the blue solid lines indicate combination trading strategies that utilize 155 anomalies. The red solid lines indicate combination trading strategies that utilize the 155 anomalies as well as SPSS. Panel A shows results using "Average rank" as the combination method. See Section 7 for details on the combination methods.
